There are no clear guidelines for anticoagulation and bridging for patients with AF in the ICU setting [56]. For patients already on anticoagulation for AF, in the absence of bleeding or significant risk factors for bleeding, anticoagulation should be continued in the ICU. Bridging anticoagulation for AF patients needing a procedure remains a controversial topic. A recent randomized controlled trial found that forgoing bridging anticoagulation was noninferior to perioperative bridging and offered less risk of bleeding [71]. It is noteworthy that the BRIDGE study excluded patients at high risk for thromboembolic events (mean CHADS2 score of the study patients was 2.3 and only 8% had previous history of stroke). Bridging therapy may offer adequate thromboprophylaxis for patients with a higher risk of stroke with the option to rapidly cease anticoagulation if bleeding occurs. Anticoagulation must, of course, be discontinued for patients with AF with active bleeding in the ICU. A discussion of reversal of warfarin and
novel oral agents in the actively bleeding patient for actively bleeding patients can be found in Chapters 88 and 93 is, and is the subject of authoritative reviews [72].

The role of anticoagulation for new-onset AF in the ICU setting is also uncertain. AF that terminates spontaneously within 48 hours of onset is rarely associated with stroke, and anticoagulation can be withheld in these patients. If AF persists for >48 hours, or it is suspected that AF has been ongoing for >48 hours at the time of admission, anticoagulation can be considered for patients with a high CHA2DS2VASc score or for those in whom cardioversion is to be considered. Intravenous heparin can achieve therapeutic anticoagulation rapidly, and its anticoagulant effect should dissipate in about an hour when stopped.

Regardless of the CHA2DS2VASc score, anticoagulation should be administered, unless contraindicated, for 4 weeks after cardioversion for AF. Atrial stunning and reduction in atrial contractility result in a thrombogenic environment and a high risk for embolic complications in the absence of anticoagulation in patients undergoing cardioversion.

Rate Control Strategy

The rate control strategy can ameliorate symptoms of AF and improve hemodynamic stability. In the outpatient setting, a heart rate <80 bpm at rest and <110 bpm with exertion were criteria for adequate rate control in the AFFIRM trial [69]. A single randomized controlled study, the RACE-II trial, demonstrated similar outcomes with a “lenient” rate control strategy with heart rate <110 bpm at rest [73]. This study had few patients with left ventricular systolic dysfunction, and most patients had heart rates <100 bpm and, hence, must be interpreted in this context.

Intravenous administration of AV nodal blocking agents can achieve timely rate control of AF with rapid ventricular response within minutes. β-Blockers such as metoprolol and esmolol and calcium channel blockers such as diltiazem and verapamil are widely used for acute rate control in the ICU [74]. The choice between these classes of agents is usually decided by individual provider preferences and the side effect profile of these medications (Table 189.1). Although rare, even cardioselective β-blockers can worsen bronchospasm, especially among ICU patients who are actively wheezing as a result of obstructive airway disease. Calcium channel blockers should be avoided for patients with poor ventricular function and heart failure. A special note must be made of preexcited AF in WPW syndrome. AV nodal blocking agents must not be used in this setting, because it can precipitate VF by increasing conduction down the
accessory pathway.

Digoxin is a second-line agent for rate control of AF, and can be administered intravenously. Compared with β-blockers and calcium channel blockers, intravenous digoxin takes longer to achieve its effects (>1 hour for onset and >6 hours for maximal effect) [74]. In addition to slower onset of action, dose adjustment for elderly and renally impaired patients, potential for lethal toxicity, including AV block and VAs, association with mortality in long-term studies all make digoxin a less favorable agent. However, it remains the only rate control medication that does not have negative inotropic effects, and can be a useful medication in the right clinical setting, for acute decompensated heart failure in particular.

Intravenous amiodarone is another option for cases of difficult rate control [75]. Clinicians with adequate experience in the use of amiodarone should guide therapy because hypotension, decompensation of heart failure, and VAs can result with its use (Table 189.1). Pharmacologic conversion to sinus rhythm can also occur, and anticoagulation must be considered based on the clinical setting as discussed previously. Dronedarone is rarely used for rate or rhythm control in ICUs and is contraindicated in patients with permanent AF and patients with acute decompensated heart failure [76].

Rhythm Control Strategy

The rhythm control strategy aims to restore sinus rhythm which can be achieved by electrical cardioversion, antiarrhythmic drug therapy, or a combination of the two. Intravenous conscious sedation is used for patients undergoing electrical cardioversion.

In the ICU setting, rhythm control is often reserved for patients who have persistently rapid ventricular rates or adverse hemodynamic consequences of AF despite an adequate trial of pharmacotherapy. As mentioned previously, hemodynamically unstable patients should be managed with cardioversion. For hemodynamically stable patients, electrical cardioversion can be performed within 48 hours of onset, and should be followed by 4 weeks of anticoagulation [77]. For patients with >48 hours or unknown duration of AF, left atrial appendage thrombus may have formed, and there are two options for management. One option is to perform transesophageal echocardiography, which can exclude a left atrial thrombus before performing cardioversion and continuing anticoagulation. If an atrial thrombus is detected, anticoagulation should be initiated and continued for 3 weeks prior to attempting cardioversion.

It is important to determine and document whether a cardioversion attempt is followed by at least temporary conversion to sinus rhythm or immediate resumption of AF [56]. If sinus rhythm is not present after
cardioversion, even temporarily, approaches to improve energy delivery such as increasing the electric output, using biphasic waveforms, adjusting location of the electrodes, or even applying pressure to optimize electrode-skin contact can be useful. Ibutilide decreases the defibrillation threshold and can be useful in this situation. If sinus rhythm is temporarily present, use of antiarrhythmics may increase the likelihood of maintenance of sinus rhythm.

For patients with long-standing AF undergoing cardioversion, there can be significant underlying sinus node dysfunction, resulting in long pauses and even sinus arrest with a ventricular escape rhythm. Providers must be ready to institute temporary transcutaneous pacing and placement of temporary transvenous pacemaker in such cases.

Pharmacologic agents can be used primarily for rhythm control or as an adjunct to electrical cardioversion. Amiodarone is perhaps the most widely used medication for this purpose. Amiodarone has a very long half-life, and there are several loading regimens available for initiation. It can be loaded intravenously and can have rate control effects in addition to enabling cardioversion. Oral amiodarone loading takes much longer to exert its antiarrhythmic effects.

Other drugs used for rhythm control include class IC agents, including propafenone and flecainide, which should be avoided in patients with structural heart disease owing to proarrhythmic effects. Class III antiarrhythmics, including dofetilide, ibutilide, and sotalol, can be used with caution in patients with structural heart disease, but can result in pro-arrhythmia because of QT prolongation (Table 189.4) [56]. These drugs should be used under expert guidance.

Atrial Flutter (AFL)

AFL is another commonly encountered arrhythmia in the ICU setting, and frequently coexists in patients with AF. “Typical” AFL is the most common type of flutter and occurs because of a reentrant circuit involving the cavitricuspid isthmus in the right atrium. The surface ECG shows sawtooth-like flutter waves, which are negative in leads II, III, and aVF and positive in lead V1. The flutter rate is typically around 300 bpm, and the refractoriness of the AV node results in 2:1, 3:1, or even 4:1 block, resulting in ventricular rates around 150, 100, and 75 bpm, respectively. Variable AV block is also common among patients receiving AV blocking agents, and can result in irregular R-R intervals. “Atypical” AFL involves reentrant circuits around atrial scars from previous surgery or ablation and can manifest with different morphology and rates on the surface ECG.

Regardless of the type of AFL, the clinical effects are similar to AF, and the management approach is similar to AF as well [56]. Rate control in
AFL can actually be more challenging than AF, and rhythm control may need to be used more often for problematic cases. Unlike AF, pharmacologic rhythm control may result in acute hemodynamic instability owing to 1:1 ventricular conduction, and immediate cardioversion may be required.

Prevention of AF for Surgical Patients

The postcardiothoracic surgery patient is particularly prone to development of AF, and an incidence as high as 25% to 50% has been reported in this group of patients. Perioperative amiodarone and β-blockade are both reasonable options to prevent AF in patients at particularly high risk of AF \[64,65\]. Sotalol and colchicine have both demonstrated efficacy for preventing the AF of cardiac surgery patients \[78,79\].

Multifocal Atrial Tachycardia

MAT is an irregular narrow complex tachycardia, characterized by at least three distinct morphologies of P waves. There is variability of both the P-R and R-R intervals \[80\]. MAT is most commonly associated with chronic medical conditions causing hypoxemia such as chronic obstructive pulmonary disease. Intravenous β-blockers or calcium channel blockers can be used for treatment of acute episodes. Correcting hypoxemia through oxygen supplemental therapies is also a key component of treatment. If more than three distinct P wave morphologies are present, but the heart rate is less than 100 bpm, then the rhythm is referred to as a wandering atrial pacemaker.

Approach to the Hemodynamically Unstable SVT

Shock is commonly encountered in the ICU setting and may be because of hypovolemic, cardiogenic, distributive, or obstructive etiologies. A variety of SVTs, including sinus tachycardia, AVNRT, AVRT, AF/AFL, and preexcited AF, can occur in patients with shock. Sinus tachycardia usually represents the physiologic compensation to hypotension. The other SVTs can be innocent bystanders or can contribute to hypotension caused by rapid ventricular rates, poor ventricular filling, and reduction in stroke volume and cardiac output. Hemodynamic instability owing to these rhythms usually occurs when the ventricular rates are very poorly controlled (>150 bpm).
All ICU providers must be familiar with the ACLS protocols for tachycardia [81]. If there is hypotension, altered mental status or ischemic chest pain as a result of the SVT, immediate synchronized cardioversion must be performed. Vagal maneuvers can be attempted if the patient is cooperative and the rhythm has a narrow complex. If the arrhythmia is definitely narrow complex, adenosine can terminate AVNRT and AVRT, and can allow diagnosis of other atrial arrhythmias.

Preexcited AF presents with a bizarre wide complex rhythm owing to rapid conduction of impulses down the accessory pathway (Fig. 189.12). Patients are frequently hemodynamically unstable, and VF can result if nodal blocking agents are used. Procainamide, a class 1a anti-arrhythmic, is the drug of choice for preexcited AF.
SECTION III: BRADYARRHYTHMIAS

Bradyarrhythmias are generally defined as heart rate below 60 bpm in symptomatic patients. Bradyarrhythmias can be largely classified into two types, (1) disorders of impulse generation, which refers to failure of the sinoatrial (SA) node to generate an initial electrical impulse and (2) disorders of impulse conduction which refers to failure in propagation electrical impulse to the myocardium (Figs. 189.4 and 189.5). Bradycardias are not always pathologic. Examples include sinus bradycardia or bradyarrhythmias in the setting of vagal response as seen in athletes or during sleeping, or a result of increased vagal tone from various factors such as carotid sinus hypersensitivity, pain, gastrointestinal distress (i.e., bowel obstruction, nausea, and vomiting), genitourinary dysfunction (i.e., urinary retention), increased intracranial pressure, hypoxia, and hypothermia [82].

Disorders of Impulse Generation

Sinus Arrhythmia

Sinus arrhythmia is the change in beat-to-beat P-P interval with unchanged morphology of the P waves (sinus rhythm) (Fig. 189.4). It is usually a normal physiologic response to alteration of vagal tone during respiration or external irritation. Certain pathology such as digitalis toxicity, ischemic heart disease, or intracranial hemorrhage can mimic the benign form of this sinus arrhythmia [83]. However, sinus arrhythmia usually does not cause hemodynamic instability, and treatment is not required.

Sinus Bradycardia

Sinus bradycardia, or sinus rhythm, with heart rate below 60 bpm, is secondary to reduced automaticity of the SA node. This happens as a result of alteration of vagal tone or pharmacologic agents such as parasympathomimetics, β-Blockers, calcium antagonists, and digitalis. Sinus bradycardia is not always indicative of pathology.

Sinus Node Dysfunction

Also referred as sick sinus syndrome, sinus node dysfunction is an intrinsic dysfunction of the SA node that leads to inappropriate
automaticity and other pacemaker foci (or junctional escape) take over control of the heart rate. Sinus node dysfunction can manifest as a combination of bradycardia and atrial tachycardia, known as “tachy-brady syndrome,” which occurs in approximately half of the patients with sinus node dysfunction [84]. Sinus node dysfunction is commonly related to age and can occur as a result of hypothyroidism, infiltrative disease, collagen vascular disease, trauma, ischemia, infection, or ion channel dysfunction [4]. Sinus node dysfunction often coexists with AV nodal disease [85].

The ability of the SA node to respond to stress decreases with age which manifests as delayed recovery after an episode of tachycardia [86]. These can be dangerous in the ICU setting, in which preexisting SA and AV nodal diseases are often exacerbated through the use of cardioinhibitory medications as well as an increase in vagal tone as a result of pain. Patients can develop sinus arrest especially immediately after sudden termination of a tachyarrhythmia which may require immediate intervention (Fig. 189.4). Further, there can be an abrupt increase in repolarization time (QT interval) during bradycardia, and the patient may be predisposed to TDP.

Disorders of Impulse Propagation

Sinoatrial Block

SA block, or SA exit block, is a failure of propagation of impulse generated by the SA node to the atrial myocardium. There are three degrees of SA block. First-degree SA block is a delayed conduction within the SA node and is undetectable on ECG. Second-degree SA block presents as intermittent conduction of SA impulse and can be divided into two types. Type I second-degree SA block is a result of progressive lengthening of the interval between impulse generation and transmission, causing successive P waves closer together with a characteristic of group beating and progressive shortening of the P-P interval until a pause is detected on ECG (Fig. 189.5). Type II second-degree SA block is a result of intermediate block where there is no progressive shortening of the P-P interval, but a sinus pause occurs. The ECG, hence, presents a missing P wave, making the duration of a P-P interval an exact multiple of the preceding P-P interval (Fig. 189.5). Finally, third-degree SA block manifests as sinus arrest (Fig. 189.5), which may require temporary pacing especially when subsidiary pacemakers (i.e., junctional rhythm) do not provide sufficient cardiac output.
Atrioventricular Block

AV block is a failure of impulse propagation at the level of the AV node that is composed of the supra- and infrahisian conduction system. The etiologies behind AV nodal disease are similar to those causing SA dysfunction. Just like SA block, there are three degrees of AV block. In first-degree AV block, there is a prolongation of the PR interval to greater than 200 ms [86,87]. There are two types of second-degree AV block. Type I second-degree AV block, also called Mobitz type I or Wenckebach-type block, is characterized by regular and progressive prolongation of the PR interval before conduction of a P wave fails to propagate to the ventricles (Fig. 189.5) [86,87]. It also involves a regular and progressive shortening of the R-R interval until an R wave is dropped. The dysfunction in impulse propagation in first- and second-degree type I AV blocks is thought to occur at the supraventricular level and generally result in a stable rhythm with narrow QRS complex and may present a physiologic response of decremental conduction in the AV node because of increasing heart rate and, therefore, rarely require intervention. Type I second-degree AV block can be a result of infranodal disease that has a poorer prognosis. One way in a clinical setting to distinguish the level of AV block is to observe the heart rate response to physiologic need (e.g., exercise in outpatient setting) or atropine.

Type II second-degree AV block or Mobitz type II block manifests as sudden failure in the propagation of an atrial impulse (dropped R wave) without a change in the preceding PR interval (Fig. 189.5) [87]. Third-degree AV block is a complete failure of propagation of the atrial impulse to the ventricles with a hallmark of AV dissociation (Fig. 189.5). In this setting, latent pacemaker foci below the level of conduction may assume control of the ventricular rhythm such as junctional or ventricular escape rhythm. Second-degree type II and third-degree AV blocks are often called high-grade AV block, which indicates the abnormal propagation at the infranodal level. Hence, it is often unstable and requires temporary or permanent pacemaker depending on their reversibility [87].

Treatment

Providers need to evaluate hemodynamic stability of the patients and distinguish reversible causes from permanent etiologies (Fig. 189.4). In the ICU setting, common causes include electrolyte disturbance, adverse effects from medications particularly β-blockers, nondihydropyridine calcium channel blockers, digoxin, antiarrhythmics, inferior or anteroseptal myocardial infarction, myocarditis, or endocarditis (particularly involving the aortic valve), any peri-AV inflammation as in
Lyme’s disease, systemic lupus erythematous, and trauma from cardiac surgery, catheter, or radiation.

**Pharmacotherapy**

Atropine may be administered in patients with bradyarrhythmias. However, atropine does not have much effect on high-grade AV blocks (i.e., infrahisian disease). It also has a short half-life, thus implementing the next treatment plan should be prepared. According to the 2015 ACLS guidelines, β-adrenergic agonists such as epinephrine and dopamine as well as cardiac pacing are the first or next step after trial of atropine [4]. In addition, isoproterenol infusion may be used to stimulate heart rate via the β-1 agonist (Table 189.4). One should be careful when using chronotropic infusions because they can exacerbate ischemia in the setting of cardiogenic shock by reducing coronary perfusion. Other treatments can be tailored toward the factors that precipitated the bradyarrhythmia. For instance, glucagon can be used in the setting of β-blocker overdose; sodium bicarbonate and hemodialysis can be used for acidosis; calcium, insulin, and hemodialysis can be used in the setting of hyperkalemia (Table 189.3).

**Pacemaker Therapy**

Pacemakers are used to improve circulatory hemodynamics by improving cardiac output by controlling the heart rate and/or rhythm. Pacemakers can be used as a permanent treatment or can be instituted as a temporizing measure [88]. There are several modalities of temporary cardiac pacing. Transcutaneous cardiac pacing is usually used in an emergent setting for patients not responsive to intravenous medications. However, owing to its instability and painful pacing, this modality should only be used as a temporizing measure for a short period of time. The pacing system is consists of a pulse generator attached to high-impedance external patch electrode pads that are applied to the anteroposterior or anterolateral positions of the patient’s bare chest. With the application of extra electrodes, these systems can sense native QRS discharge that allows them to have antibradycardia, antitachycardia, and defibrillation capacity. The need for continued pacing can be evaluated by gradually decreasing pacing output, resulting in returning of stable rhythm.

Transvenous endocardial pacing is predominantly used for patients with unstable bradyarrhythmias that will last for a period of time while waiting for permanent pacemaker implantation or resolving of underlying etiology. In transvenous pacing, the heart is directly paced using catheters placed in the apex of the right ventricle. Central venous
access is achieved using an introducer sheath through the jugular, subclavian, femoral, or brachial veins [89]. Pacing catheters are then advanced under fluoroscopic guidance. A chest X-ray is then used to confirm placement of the catheter, and the pacing and sensing thresholds are tested. The catheters are then connected to an external pacing generator. Transvenous pacing is more easily tolerated and more reliable than transcutaneous pacing but is associated with a greater risk of complications, including hematoma, induction of VA, myocardial puncture, pneumothorax, bleeding, lead dislodgment, and infection leading to sepsis [89–91].

Hypotension and hemodynamic instability are frequently encountered clinical problems in the intensive care setting. When the mean arterial blood pressure falls below approximately 60 mmHg, end-organ perfusion becomes compromised and is manifested clinically as cool skin, decreased urine output, and altered mental status. Cornerstones of management include volume resuscitation and therapy directed toward the underlying cause of hypotension (e.g., cardiac pacing for bradycardia; cardioversion or defibrillation for tachyarrhythmias; blood transfusion for gastrointestinal bleeding; and corticosteroids for adrenal insufficiency). When these measures fail to restore blood pressure and vital organ perfusion or while awaiting their availability, administration of intravenous vasoactive agents may be necessary. This chapter reviews the general management of the hypotensive patient with an emphasis on coronary care and the pharmacologic properties of commonly used vasopressor and positive inotropic agents. An overview of shock (see Chapter 37); volume resuscitation (see Chapter 37); sepsis (see Chapter 39); and the use of intra-aortic balloon counterpulsation and mechanical circulatory support devices (see Chapter 196) is given elsewhere.

GENERAL APPROACH TO THE HYPOTENSIVE PATIENT IN THE CORONARY CARE UNIT
The assessment of the hypotensive patient begins with accurate measurement of the blood pressure and rapid correlation with clinical signs of hypoperfusion. Blood pressure should be measured in both arms and confirmed by another examiner. This practice is especially important when automated devices are used to make these measurements in the setting of tachyarrhythmias or respiratory distress. For patients with peripheral arterial disease, upper extremity blood pressure should also be compared to measurements in the legs in the supine position. In rare circumstances, true central aortic pressure may differ significantly from peripherally obtained blood pressures and can only be confirmed by invasive measurement during diagnostic catheterization. This situation should be suspected when clinical features of hypoperfusion do not accompany low blood pressure.

Hypotension is generally defined as a mean arterial pressure of less than 60 mmHg and/or a systolic blood pressure less than 100 mmHg. However, higher values may be consistent with clinically relevant hypotension if there are concomitant clinical signs of hypoperfusion such as mental status changes, oliguria, pallor, and cool extremities. If clinically relevant hypotension cannot be rapidly corrected, invasive monitoring with an arterial line should be considered, especially when vasoactive medications are employed. Central venous catheterization should also be considered to monitor intravascular volume, because volume status is often dynamic in the hypotensive patient and multiple mechanisms of hypotension may be simultaneously present. A central venous catheter can also be used for rapid administration of drugs and intravenous fluids. Indwelling urinary catheterization should also be employed to assess hourly urine output as an index of end-organ perfusion.

The history and physical examination should be directed toward establishing the primary mechanism and etiology of hypotension. Primary mechanisms include hypovolemia, low cardiac output, and vasodilation. Assessing volume status is critical; if not discernible from the bedside evaluation (jugular venous pressure, skin turgor, urine output, and orthostasis), echocardiography or invasive measurement of the central venous pressure should be obtained. If there are clinical reasons to suggest a dissociation of right and left ventricular hemodynamics (i.e., right ventricular infarction), pulmonary artery catheterization may be required to measure the left ventricular filling pressure. Warm well-perfused skin and extremities despite hypotension may suggest low systemic vascular resistance and a vasodilatory state,
whereas cool clammy skin and extremities suggest vasoconstriction as a compensatory response to a low output syndrome. A narrow pulse pressure may also suggest reduced cardiac output. If a putative mechanism of hypotension cannot be ascertained from bedside assessment, pulmonary artery catheterization can be used to characterize the hemodynamic profile. This strategy is especially useful when more than one mechanism is present (for example, a large myocardial infarction complicated by pneumonia, leading to cardiogenic shock along with vasodilatory shock).

Initial management strategies are directed at the primary cause of hypotension and addressed later in this chapter. In general, therapy is guided by the primary pathophysiologic mechanism underlying the hypotension (e.g., volume resuscitation for hypovolemia; positive inotropes for low cardiac output; and vasopressors for vasoplegia). The pace and aggressiveness of therapeutic intervention are guided by the presence or absence of clinical signs of hypoperfusion. For example, holding vasodilators may be sufficient for the hypotensive patient without changes in mental status or urine output. In contrast, the acutely hypotensive patient with clinical shock needs rapid resuscitation with intravascular volume expansion and usually vasoactive therapy.
ADRENERGIC RECEPTOR PHYSIOLOGY

Most vasopressor and positive inotropic agents currently available for use are sympathomimetic amines that exert their action by binding to and stimulating adrenergic receptors. To better understand the similarities and differences among these agents, a basic knowledge of adrenergic receptor distribution and function is helpful [1].

The adrenergic receptors that are most relevant to the management of hypotension are the $\alpha_1$, $\beta_1$, and $\beta_2$ receptors. $\alpha_1$-Adrenergic receptors are present in smooth muscle cells of many vascular beds, including the arterioles supplying the skin, mucosa, skeletal muscle, and kidneys, as well as the peripheral veins. $\alpha_1$-Adrenergic stimulation causes vasoconstriction and is the most common mechanism of vasopressor action. The presence of $\alpha_1$ receptors has also been demonstrated in the myocardium, where stimulation appears to result in a positive inotropic effect with little change in heart rate. $\beta_1$-Adrenergic receptors are the predominant adrenergic receptor type in the heart and they mediate positive inotropic, chronotropic, and lusitropic responses. Stimulation of $\beta_2$-adrenergic receptors causes relaxation of smooth muscle cells in bronchial, gastrointestinal, and uterine muscle, as well as vasodilation of skeletal muscle. $\beta_3$-adrenergic receptors, which are located mainly in adipose tissue, are involved in the regulation of lipolysis and thermogenesis and do not play a role in hemodynamic stability. Other relevant receptors are the dopaminergic receptors ($DA_1$ and $DA_2$), which mediate renal, coronary, cerebral, and mesenteric vasodilation, and cause a natriuretic response.

The receptor selectivity of sympathomimetic amines can be drug and dose dependent. For example, $\beta_2$ receptors are more sensitive to epinephrine than are $\alpha_1$ receptors. Thus, at low doses of epinephrine, the vasodilatory effect of $\beta_2$ receptors predominates, whereas at high doses, $\alpha_1$-mediated vasoconstriction overcomes the $\beta_2$ effect and increases systemic vascular resistance. The dose-dependent actions of dopamine have also been well established.

The overall clinical effects of vasoactive agents depend not only on the outcome of direct adrenergic receptor stimulation, but also on the reflex response of homeostatic forces. For example, stimulation of $\beta_1$-adrenergic receptors by norepinephrine would be expected to cause an increase of heart rate; however, norepinephrine-mediated $\alpha_1$-adrenergic stimulation
induces a reflex increase of vagal tone that cancels out its positive chronotropic effects. The action of some drugs (e.g., dopamine and ephedrine) is further complicated by their ability to stimulate release of stored endogenous catecholamines.
COMMONLY USED VASOPRESSORS AND POSITIVE INOTROPES

The armamentarium of vasoactive agents has changed little since the 1980s [2]. Commonly used drugs with vasopressor activity are dopamine, epinephrine, norepinephrine, phenylephrine, and ephedrine. Vasopressin is a newer alternative to adrenergic vasopressors. Agents with positive inotropic activity that are useful for the treatment of hypotension include dobutamine, dopamine, epinephrine, and isoproterenol. Table 190.1 summarizes the receptor activity and hemodynamic effects of these drugs.

Dopamine

Dopamine is an endogenous catecholamine that functions as a central neurotransmitter and a synthetic precursor of norepinephrine and epinephrine. When administered intravenously, the effects of dopamine are mediated by dose-dependent stimulation of dopaminergic and adrenergic receptors, and by stimulation of norepinephrine release from nerve terminals.

At low doses (less than 5 μg/kg/min), dopamine predominantly stimulates dopaminergic receptors in renal, mesenteric, and coronary vessels with minimal adrenergic effects. In normal subjects, the so-called renal-dose dopamine augments renal blood flow, glomerular filtration rate, and natriuresis, with little effect on blood pressure. Low-dose dopamine has frequently been used by itself or in combination with other drugs as a renoprotective agent. However, the efficacy and safety of this strategy remain controversial [3]. Although mechanistic studies have demonstrated renal vasodilatory effects of dopamine among patients with heart failure [4], a randomized placebo-controlled trial in 360 patients with acute heart failure and renal dysfunction demonstrated no effect of low-dose dopamine on renal function or decongestion, and no difference in symptoms or clinical outcomes compared to placebo [5]. Similar neutral effects of low-dose dopamine on renal function, and intensive care unit (ICU) and hospital length of stay have been observed in critically ill patients with early renal dysfunction [6]. Moderate doses of dopamine (5 to 10 μg/kg/min) stimulate β₁-adrenergic receptors in the myocardium, augmenting cardiac output by increasing contractility and, to a lesser extent, heart rate (Fig. 190.1). In addition, vasoconstriction mediated by serotonin and dopaminergic receptors may occur [7]. At higher doses (greater than 10 μg/kg/min), α₁-adrenergic receptor stimulation predominates, resulting in systemic arteriolar vasoconstriction. The overall effects of dopamine at the highest doses resemble those of norepinephrine (see later). However, it should be remembered that there is a great deal of overlap in the dose-dependent effects of dopamine in critically ill patients [1,3].
Moderate- to high-dose dopamine is a mainstay in the treatment of hypotension. In studies of fluid-resuscitated patients with septic shock, dopamine produced a mean increase in mean arterial pressure of approximately 25%, primarily owing to an increase of cardiac index and, to a lesser extent, systemic vascular resistance [3]. In the setting of hyperdynamic septic shock when excessive vasodilation is the primary source of hypotension, addition or substitution of a more potent \(\alpha\)-adrenergic agonist such as norepinephrine may be more effective. Moreover, evidence of worsening splanchnic oxygen utilization with the use of high-dose dopamine has made it a less attractive agent.

By itself or in combination with other agents, dopamine may be used at moderate doses for the management of patients with acute heart failure and hypotension. Venodilating agents (e.g., nitroprusside and nitroglycerin) may be added to moderate the tendency of dopamine to increase cardiac-filling pressures [8]. Dopamine may also be combined with dobutamine for added inotropic effects or used at low doses to augment diuresis [9], although the benefits of “renal-dose” dopamine remain unproven and other agents may be more effective for preserving renal function of critically ill patients [10]. For patients with symptomatic bradycardia unresponsive to atropine, particularly when associated with hypotension, dopamine can be effective while preparing for emergent transvenous temporary pacing [11].

The use of dopamine is associated with several adverse effects, including tachycardia, tachyarrhythmias, and excessive vasoconstriction. Although these effects are generally dose dependent, in individual patients there may be substantial overlap of receptor affinity such that even at low doses dopamine may result in toxicity [5]. For patients with ischemic heart disease, increased myocardial oxygen consumption
coupled with some degree of coronary vasoconstriction with high-dose dopamine can result in myocardial ischemia. As with other positive inotropes, dopamine can increase flow to poorly oxygenated regions of the lung and cause shunting and hypoxemia. In addition, dopamine has been shown to depress minute ventilation of normoxic patients with heart failure [12]. When dopamine is used for patients with acute heart failure, increased venous tone and pulmonary arterial pressure may exacerbate pulmonary edema in the setting of already high cardiac filling pressures. Despite these caveats, oxygen saturation generally remains constant owing to improved hemodynamics.

There is mounting evidence that dopamine adversely effects splanchnic perfusion at doses usually required to treat septic shock. A small, randomized study of patients with sepsis using selective splanchnic and hepatic cannulation showed that infusion of dopamine was associated with a disproportionate increase of splanchnic oxygen delivery compared with oxygen extraction (65% vs. 16%). In contrast, norepinephrine produced better-matched increases in oxygen delivery and extraction (33% vs. 28%) [13]. Another study showed that among patients with septic shock randomly assigned to treatment with norepinephrine or dopamine, gastric intramucosal pH worsened significantly among patients treated with dopamine despite similar improvements in mean arterial pressure [14]. Thus, the use of dopamine for septic shock may be associated with splanchnic shunting, impairment of gastric mucosal oxygenation, and increased risk of gastrointestinal bleeding [3].

**Epinephrine**

Epinephrine is an endogenous catecholamine that is a potent nonselective agonist of α- and β-adrenergic receptors. Stimulation of myocardial β₁ and β₂ receptors increases contractility and heart rate, resulting in a rise in cardiac output (Fig. 190.2). Cardiac output is further augmented by an increase in venous return as a result of α₁-mediated venoconstriction. Blood flow to skeletal muscles is increased owing to β₂-mediated vasodilation. With very low-dose infusions of epinephrine (0.01 to 0.05 μg/kg/min), β-adrenergic–mediated positive chronotropic and inotropic effects predominate. Diastolic blood pressure and overall peripheral vascular resistance may actually decrease owing to vasodilation of skeletal muscle. With higher doses of epinephrine, stimulation of α-adrenergic receptors in precapillary resistance vessels of the skin, mucosa, and kidneys outweighs β₂-mediated vasodilation in skeletal muscle, causing increased mean and systolic blood pressure [1].

Epinephrine plays a central role in cardiovascular resuscitation (see Chapter 14) and the management of anaphylaxis (see Chapter 69).
Epinephrine is also used to reverse hypotension with or without bradycardia after cardiopulmonary bypass or cardiac transplantation [15]. Because of its adverse effects on splanchnic [16] and renal blood flow and potential for inducing myocardial ischemia and tachyarrhythmias, epinephrine has generally been regarded as a second-line agent in the management of septic shock [3,17]. However, a randomized trial showed no difference in efficacy or safety between epinephrine alone versus norepinephrine plus dobutamine for patients with septic shock [18]. For patients with symptomatic bradycardia and hypotension who have failed atropine or external pacing, epinephrine may be used to stabilize the patient while awaiting more definitive therapy (e.g., transvenous placement of a temporary or permanent pacemaker) [19]. When used to treat hypotension, epinephrine is given as a continuous infusion starting at a low dose (0.5 to 1.0 μg per minute) and titrating up to 10 μg per minute as needed. Continuous infusions of epinephrine may cause restlessness, tremor, headache, and palpitations. Epinephrine should be avoided for patients taking β-adrenergic antagonists, because unopposed α-adrenergic vasoconstriction may cause severe hypertension and cerebral hemorrhage.

**Norepinephrine**

Norepinephrine is an endogenous catecholamine that is a potent β₁- and α₁-adrenergic agonist, with little β₂ activity. The main cardiovascular effect of norepinephrine is dose-dependent arterial and venous vasoconstriction owing to α-adrenergic stimulation (Fig. 190.2). The positive inotropic and chronotropic effects of β₁ stimulation are generally counterbalanced by the increased afterload and reflex vagal activity induced by the elevated systemic vascular resistance. Thus, heart rate and cardiac output usually do not change significantly, although cardiac output may increase or decrease depending on vascular resistance, left ventricular function, and reflex responses [7].
Norepinephrine, when infused at doses ranging from 0.5 to 30.0 μg per minute, is a potent vasopressor. Although traditionally reserved as a second-line agent or used in addition to other vaspressors in cases of severe distributive shock, norepinephrine has emerged as the agent of choice for the management of hypotension in hyperdynamic septic shock [18,20]. In a small, prospective double-blind trial, Martin et al. [21] randomized patients with hyperdynamic septic shock to dopamine or norepinephrine titrated to a mean arterial pressure greater than or equal to 80 mmHg or systemic vascular resistance greater than 1,100 dynes/s/cm$^{-5}$, or both. Although only 5 of 16 patients randomized to dopamine were able to achieve these endpoints, 15 of 16 patients randomized to norepinephrine were successfully treated with a mean dose of 1.5 μg/kg/min. Moreover, 10 of the 11 patients who remained hypotensive on high-dose dopamine improved with the addition of norepinephrine. A subsequent prospective, nonrandomized, observational study suggested that in adults with septic shock treated initially with high-dose dopamine or norepinephrine, the use of norepinephrine was associated with improved survival [22]. More recently, the Sepsis Occurrence in Acutely Ill Patients (SOAP) II trial
group randomized 1,679 patients with shock to receive either dopamine or norepinephrine as first-line vasopressor therapy to restore and maintain blood pressure [23]. There was no significant difference between the groups in rate of death at 28 days (52.5% vs. 48.5%, respectively; OR with dopamine, 1.17; 95% confidence interval, 0.97 to 1.42; \( p = 0.10 \)) (Fig. 190.3A); however, there were more arrhythmic events with dopamine (24.1% vs. 12.4%, \( p < 0.0001 \)). In a subgroup analysis of patients with cardiogenic shock (\( n = 280 \)), dopamine was associated with an increased risk of death (\( p = 0.03 \)) (Fig. 190.3B). Meta-analyses of norepinephrine versus dopamine in the treatment of septic shock have also suggested that norepinephrine is associated with reduced mortality and less arrhythmic events [24]. In the setting of sepsis, norepinephrine improves renal blood flow and urine output [25], although large doses may be required to achieve these effects because of \( \alpha \)-receptor downregulation [3].
28-day survival in patients with shock randomized to norepinephrine (blue line) or dopamine (red line). Panel B, Forest plot for predefined subgroup analysis according to type of shock. A total of 1,044 patients were in septic shock, 280 were in cardiogenic shock, and 263 were in hypovolemic shock.

Adverse effects of norepinephrine include increased myocardial oxygen consumption causing ischemia and renal and mesenteric vasoconstriction. Renal ischemia may be of particular concern for patients with hemorrhagic shock. Norepinephrine can also cause necrosis and sloughing at the site of intravenous injection owing to drug extravasation. Norepinephrine is relatively contraindicated for patients with hypovolemia. As previously discussed, the overall effect of norepinephrine on gut mucosal oxygenation of septic patients compares favorably with that of high-dose dopamine.

Phenylephrine

Phenylephrine is a synthetic sympathomimetic amine that selectively stimulates α₁-adrenergic receptors. When administered intravenously, phenylephrine causes dose-dependent arterial vasoconstriction and increases peripheral vascular resistance. As blood pressure rises, activation of vagal reflexes causes slowing of the heart rate.

Phenylephrine, infused at 40 to 180 μg per minute, is commonly used for the management of anesthesia-induced hypotension [26,27] and hyperdynamic septic shock. Its rapid onset of action, short duration, and primary vascular effects make it an ideal agent for treating hemodynamically unstable patients in the intensive care setting. However, there are few data regarding its relative efficacy compared with older vasopressors such as norepinephrine and dopamine. In one small study of fluid-resuscitated patients with septic shock, the addition of phenylephrine to dobutamine or dopamine increased mean arterial pressure and systemic vascular resistance without a change in heart rate [28]. In addition, urine output improved, whereas serum creatinine remained stable. In another study, patients with septic shock were randomized to initial hemodynamic support with phenylephrine or norepinephrine [29]. There were no differences in systemic or regional hemodynamics between the groups. The absence of β-adrenergic agonist
activity at usual doses (phenylephrine activates $\beta$ receptors only at much higher doses) makes phenylephrine an attractive agent for the management of hypotension in clinical situations where tachycardia or tachyarrhythmias, or both, limit the use of other agents [3]. As with other vasopressors, high-dose phenylephrine may cause excessive vasoconstriction. In addition, patients with poor ventricular function may not tolerate the increased afterload induced by $\alpha_1$-stimulation [28].

Compared to epinephrine and norepinephrine, phenylephrine is less likely to decrease microcirculatory blood flow in the gastrointestinal tract [30]. When used to treat hypotension during spinal anesthesia for cesarean delivery, phenylephrine dose requirements may be affected by $\beta_2$-adrenoceptor genotype [31].

**Ephedrine**

Ephedrine is a naturally occurring sympathomimetic amine derived from plants. Its pharmacologic action results from direct nonselective activation of adrenergic receptors, as well as stimulation of norepinephrine release from storage sites. Although ephedrine is less potent and longer acting (half-life, 3 to 6 hours) than epinephrine, its hemodynamic profile is similar and includes cardiac stimulation and peripheral vasoconstriction.

Ephedrine is rarely used in the critical care setting except in the temporary treatment of hypotension induced by spinal anesthesia [26]. Ephedrine does not appear to compromise uterine blood flow and is considered an alternative to phenylephrine in the treatment of anesthesia-induced hypotension of the obstetric patient [32]. However, prophylactic use for pregnant woman undergoing Caesarean section is not recommended because it may cause hypertension and tachycardia [33]. Ephedrine can be administered at doses of 10 to 25 mg, given as an intravenous bolus every 5 to 10 minutes, with the total dose not to exceed 150 mg in 24 hours. For healthy women undergoing elective cesarean delivery that develop hypotension, pharmacogenomic data suggests that $\beta_2$-adrenoceptor genotype may affect dose requirements [34]. Adverse effects of ephedrine include myocardial ischemia and excessive vasoconstriction; in the setting of delivery, ephedrine can cause fetal acidosis.

**Isoproterenol**

Isoproterenol is a synthetic sympathomimetic amine with potent nonselective $\beta$-adrenergic activity and little effect on $\alpha$-adrenergic receptors. Its major cardiovascular effect is increased cardiac output owing to direct positive inotropic and chronotropic effects (Fig. 190.2).
Isoproterenol also increases heart rate by increasing atrioventricular nodal conduction. Systemic and pulmonary vascular resistances decrease owing to $\beta_2$-mediated vasodilation of skeletal muscle and pulmonary vasculature, respectively. Reduced peripheral resistance typically causes a fall of mean arterial and diastolic blood pressure, whereas systolic blood pressure is unchanged or rises modestly owing to increased cardiac output. Coronary blood flow remains unchanged, which in the face of increased myocardial oxygen demand can produce ischemia among patients with ischemic heart disease. In addition, stimulation of myocardial $\beta_2$-receptors can cause arrhythmias via increased dispersion of repolarization [35].

Stimulation of $\beta$-adrenergic receptors in the heart by isoproterenol increases the risk of excessive tachycardia, tachyarrhythmias, and myocardial ischemia. Given the likelihood of toxicity and the availability of alternative drugs, isoproterenol is no longer used as an inotropic agent; rather, its use is limited to the temporary treatment of hemodynamically significant bradycardia unresponsive to atropine while awaiting more definitive treatment with an external or transvenous pacemaker. The starting infusion rate for isoproterenol is 1 $\mu$g per minute, and this can be titrated up to 10 $\mu$g per minute to achieve the desired response (e.g., for bradycardia, titrated to a heart rate of 60 beats per minute or higher, depending on the blood pressure response). Other uses for isoproterenol include “chemical” overdrive pacing for torsades de pointes refractory to magnesium [36], and temporary inotropic and chronotropic support after cardiac transplantation [37]. Side effects of isoproterenol include palpitations, headache, flushing, and rarely paradoxical bradycardia [38].

**Dobutamine**

Dobutamine is a synthetic sympathomimetic amine that was derived from isoproterenol in an attempt to create a less arrhythmogenic positive inotrope with minimal vascular effects. Although initially thought to be a selective $\beta_1$-adrenergic agonist, its mechanism of action appears to be more complex. Dobutamine is available for clinical use as a mixture of two enantiomeric forms with different pharmacologic properties. Ruffolo et al. [39] showed that although both stereoisomers are nonselective $\beta$-agonists, the positive isomer is several times more potent. In addition, the two isomers have opposing effects on $\alpha$-adrenergic receptors: the positive isomer is an $\alpha$-antagonist and the negative isomer is a potent $\alpha_1$-agonist. The overall effect of the racemic mixture is potent nonselective $\beta$- and mild $\alpha$-adrenergic stimulation [39].

Cardiac contractile force is enhanced by $\beta_1$- and $\alpha$-adrenergic stimulation. Heart rate may also increase, but to a lesser extent than
occurs with isoproterenol or dopamine (Fig. 190.1). In contrast to
dopamine, dobutamine decreases cardiac filling pressures, making it a
preferred agent for the treatment of patients with acute heart failure [40].
Systemic vascular resistance is modestly reduced or may remain
unchanged, because $\alpha_1$-mediated vasoconstriction is counterbalanced by
$\beta_2$-mediated vasodilation and reflex withdrawal of sympathetic tone that
typically occurs in response to increased cardiac output. Dobutamine has
no effect on dopaminergic receptors; however, renal blood flow often
increases in proportion to the increase of cardiac output [41] because of
reduced renal sympathetic activity [42].

Dobutamine, by itself or in combination with other vasoactive drugs, is
useful in the temporary support of myocardial function of patients with
hypotension and poor end-organ perfusion, including those with acute
heart failure as well as patients with concomitant septic shock and
depressed cardiac function. Among patients with cardiogenic shock, the
effect of dobutamine on systemic vascular resistance and blood pressure
is difficult to predict. Therefore, when used in this setting, it is often
administered in combination with dopamine [9,40].

Dobutamine is generally initiated at an infusion rate of 2 $\mu$g/kg/min
and can be titrated up to 15 $\mu$g/kg/min or higher to achieve the desired
hemodynamic or clinical effects, or both. Side effects that may limit dose
titration include increased heart rate and exacerbation of
supraventricular and ventricular arrhythmias. As with other positive
inotropic agents, increased myocardial oxygen consumption can worsen
cardiac ischemia, and short-term dobutamine therapy has been
associated with excess mortality [43,44]. Although systolic and mean
arterial blood pressures typically increase, hypotension may occur when
dobutamine is administered to a volume-depleted patient. Some patients
with advanced heart failure may be resistant to dobutamine owing to $\beta$-
receptor hyporesponsiveness or may develop tolerance after several
days of a continuous infusion [45]. Chronic dobutamine therapy may also
cause an eosinophilic or hypersensitivity myocarditis [46], leading to
further hemodynamic deterioration, as well as late acute cellular rejection
following heart transplantation [47].

Vasopressin

Arginine vasopressin, an antidiuretic hormone, has emerged as a safe
alternative to adrenergic vasopressors for the treatment of refractory
vasodilatory shock. The mechanism of action of vasopressin has not been
fully elucidated, but likely involves binding to $V_1$ receptors on vascular
smooth muscle cells. Although it has minimal pressor activity among
normal subjects, vasopressin has been shown to improve blood pressure
for patients with sepsis [48] and in patients with vasodilatory shock after
cardiopulmonary bypass [49] (Table 190.2). In these initial studies, vasopressin was initiated at a dose of 0.1 units per minute; for subjects maintaining a mean arterial pressure greater than 70 mmHg, vasopressin was tapered to 0.01 units per minute and then discontinued. Notably, many patients in these studies were poorly responsive to intravenous catecholamine support and had inappropriately low vasopressin levels before treatment consistent with a defect in baroreflex-mediated vasopressin secretion. It remains unclear, however, whether the benefits of vasopressin are confined to patients with relative vasopressin deficiency, hypersensitivity, or both.

Table 190.2 Summary of Advances in the Management of Hypotension

- Norepinephrine is recommended as a first-line agent to treat hypotension in the setting of septic shock [3,23].
- Vasopressin improves blood pressure in patients with sepsis [48] or vasodilatory shock after cardiopulmonary bypass [49]. Newer analogs of vasopressin, terlipressin and selepressin, are under development [58,59].
- Stress-dose steroids improve hemodynamics and may reduce mortality in septic shock if adrenocortical insufficiency is present [83,85]. Doses of hydrocortisone should not exceed 200–300 mg/d [3].
- Methylene blue is effective for refractory hypotension following cardiopulmonary bypass [69,70] and may be useful in preventing vasoplegia in high-risk surgical patients [71].

Russell et al. [50] randomized 778 patients with septic shock who were receiving a minimum of 5 μg per minute of norepinephrine to receive either low-dose vasopressin (0.01 to 0.03 units per minute) or norepinephrine (5 to 15 μg per minute) in addition to open-label vasopressors. After 28 days, there was no significant difference in mortality rates between the vasopressin and norepinephrine groups (35.4% and 39.3%, respectively; \( p = 0.26 \)) (Fig. 190.4). However, for patients with less severe septic shock (prospectively defined as those receiving treatment with less than 15 μg per minute of norepinephrine), mortality was lower for the vasopressin group (26.5% vs. 35.7%, \( p = \))
In a meta-analysis of 9 trials covering 998 participants, vasopressin use for vasodilatory shock was associated with a 13% reduced risk of mortality compared to norepinephrine [51].

Vasopressin may also be effective for the treatment of cardiac arrest unresponsive to epinephrine and defibrillation [52]. In 2010, revised guidelines for advanced cardiovascular life support (ACLS) recommended vasopressin as an alternative to epinephrine for the treatment of adult shock-refractory ventricular fibrillation, as well as an adjunctive agent in the treatment of patients with vasodilatory shock, such as septic shock or sepsis syndrome, refractory to standard therapy [53]. However, vasopressin was removed from the 2015 ACLS Cardiac Arrest Algorithm [7] in recognition of equivalence of effect with other available interventions (e.g., epinephrine). A meta-analysis of cardiac arrest trials demonstrated no significant differences between vasopressin and epinephrine groups in failure of return of spontaneous circulation, death within 24 hours, or death before hospital discharge [54]. In a randomized clinical trial of 2,894 patients with out-of-hospital cardiac arrest
receiving advanced cardiac life support, the combination of vasopressin (40 International Units) and epinephrine (1 mg) did not improve outcomes compared to epinephrine alone: return of spontaneous circulation, 28.6% versus 29.5%; survival to hospital admission, 20.7% versus 21.3%; and survival to hospital discharge, 1.7% versus 2.3%; respectively [55]. In the setting of vasodilatory shock, vasopressin can be administered as a continuous infusion at 0.01 to 0.07 units per minute. Potential adverse effects of vasopressin include excess vasoconstriction causing end-organ ischemia including myocardial ischemia and mesenteric ischemia, and hyponatremia. Cardiac output may also worsen owing to increased afterload. Rebound hypotension is common following withdrawal of vasopressin and can be avoided by slowly tapering the dose.

Newer vasopressin receptor agonists, including terlipressin and selepressin, are undergoing clinical investigation [51,56]. Terlipressin is a synthetic, long-acting analog of vasopressin that is approved in Europe for the treatment of esophageal variceal bleeding and hepatorenal syndrome. In a pilot study of patients with septic shock despite adequate volume resuscitation, a continuous infusion of low-dose terlipressin (1.3 μg/kg/h) was effective for reversing arterial hypotension and reducing catecholamine requirements [57]. Compared with vasopressin or norepinephrine, terlipressin was associated with less rebound hypotension upon discontinuation. Adverse effects associated with terlipressin include hypertension, bradycardia, skin pallor, and reduction of platelet count. In preclinical studies, selepressin, a selective, short-acting vasopressin V\(_{1a}\) agonist, has been shown to limit myocardial ischemia, reduce pulmonary edema and improve short-term outcomes compared to vasopressin and norepinephrine [58,59].

**Adjunctive and Investigational Agents**

In addition to the agents discussed previously, the phosphodiesterase inhibitor milrinone is commonly used for the management of acute heart failure. Milrinone increases cardiac contractility by directly inhibiting the breakdown of cyclic adenosine monophosphate, resulting in an increase of intracellular calcium [60]. In addition, phosphodiesterase inhibition of vascular smooth muscle causes systemic and pulmonary vasodilation [61]. Because milrinone does not require binding to adrenergic receptors to exert its effects, it is particularly useful for the treatment of patients taking β-adrenergic antagonists [62] or those with advanced heart failure that may be resistant to β-agonist stimulation with dobutamine [45]. Milrinone is generally administered as an intravenous loading dose (50 μg per kg), followed by a continuous infusion at doses ranging from 0.25 to 0.75 μg/kg/min. As it is renally excreted, milrinone should be dose-
adjusted when renal failure is present; and for all patients, milrinone should be titrated cautiously, using invasive hemodynamic monitoring. Because it is a potent vasodilator, however, milrinone should be avoided in the treatment of patients with frank hypotension, and is contraindicated in patients with severe aortic stenosis. Similarly, the use of levosimendan [63], a calcium sensitizer with phosphodiesterase and potassium channel inhibitor properties, may be limited by hypotension [64]. In a randomized, double-blind study of 1,327 patients with acute heart failure, intravenous levosimendan showed no benefit compared to dobutamine for reducing all-cause mortality at 180 days (26% vs. 28%, respectively; hazard ratio, 0.91; 95% confidence interval, 0.74 to 1.13; \( p = 0.40 \)), and increased the incidence of atrial fibrillation [65]. Although approved for use in Europe, levosimendan remains an investigational agent in the USA.

With the exception of vasopressin, all currently available vasopressors exert their action through stimulation of \( \alpha \)-adrenergic receptors. This approach is often associated with worsening splanchnic perfusion, and in some patients may prove ineffective for restoring mean arterial pressure. Evidence of the central role of endothelium-derived nitric oxide (NO) for mediating vasodilation [66] led to the development of substances that interfere with NO production or activity. Several investigators have shown that analogs of L-arginine, the synthetic precursor of NO, can competitively inhibit NO synthetic enzymes, thereby decreasing NO production and increasing mean arterial pressure of patients with septic shock [67]. Others have shown that inhibition of guanylate cyclase, the target enzyme of NO, with methylene blue is effective in increasing mean arterial pressure, reducing the need for vasopressors and maintaining oxygen transport during septic shock [68]. Methylene blue has also been used successfully to treat refractory hypotension for patients with vasoplegia following cardiopulmonary bypass (Table 190.2) [69,70], and may be used to prevent vasoplegia of high-risk cardiac surgical patients [71]. However, the overall safety and efficacy of NO inhibition remains unproven. A large, randomized, placebo-controlled trial of the NO synthase inhibitor 546C88 for sepsis was stopped prematurely owing to excess mortality at 28 days (59% vs. 49%, \( p < 0.001 \)) in the active treatment arm [67]. As with adrenergic agents, lack of selectivity may have contributed to undesirable effects. In addition, the FDA warns that the coadministration of methylene blue with certain selective serotonin reuptake inhibitors may trigger the serotonin syndrome, a potentially lethal condition with cognitive, autonomic, and somatic manifestations [72,73]. More selective NO inhibitors are currently under investigation.

Another novel agent that was approved for the treatment of patients with severe sepsis, but then withdrawn from the market, is recombinant human activated protein C (drotrecogin alfa activated) [74]. In the
Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis study, 1,690 patients with systemic inflammation and organ failure owing to acute infection (71% of whom presented with shock) were randomized to receive drotrecogin alfa activated or placebo as a continuous infusion for 4 days [75]. Drotrecogin alfa activated reduced all-cause mortality by 19%, but tended to increase the risk of serious bleeding. Based on this study, drotrecogin alfa activated was recommended for the treatment of patients with severe sepsis and high risk of death (Apache II score greater than 25). In a subsequent study of patients with severe sepsis and low risk of death (Apache II score less than or equal to 25), there was no beneficial effect of drotrecogin alfa activated on either in-hospital or 28-day mortality [76]. The risk of serious bleeding was higher (2.4% vs. 1.2%, \( p = 0.02 \)) in the drotrecogin alfa activated group. Finally, in a randomized, controlled trial (PROWESS-SHOCK) of 1,697 patients with septic shock and clinical hypoperfusion despite fluids and vasopressors, the addition of drotrecogin alfa activated did not significantly reduce mortality at 28 or 90 days [77]. A randomized controlled study of drotrecogin alfa activated in children with severe sepsis also showed no benefit [78]. The 28-day mortality rates were 17.2% and 17.5% in the drotrecogin alfa activated and placebo groups, respectively (\( p = 0.93 \)).

Several hormones including cortisol and thyroxine are known to play important roles in the maintenance of vascular tone, and their absolute or relative deficiency may contribute to hypotension in the critically ill patient. The adverse effects of hypothyroidism (see Chapter 142) and adrenal insufficiency (see Chapter 139) on central and peripheral hemodynamics have been well described. Although the routine use of high-dose corticosteroids has not been shown to be beneficial in the treatment of sepsis, the administration of stress-dose steroids to patients suspected of having relative impairment of adrenocortical response may be helpful for restoring normal hemodynamics and improving outcomes.

In the 1990s, three small trials of patients with septic shock demonstrated decreased duration of shock with steroid treatment [79–81]. Subsequently, Annane et al. [82] randomized 300 patients with septic shock to receive hydrocortisone (50 mg intravenous bolus every 6 hours) and fludrocortisone (50 \( \mu \)g by mouth once daily) or matching placebos for 7 days. Patients were enrolled after undergoing a short corticotropin stimulation test. In the 229 nonresponders to corticotropin (i.e., with relative adrenal insufficiency), treatment with corticosteroids increased vasopressor withdrawal (57% vs. 40%, \( p = 0.001 \)) and decreased mortality (53% vs. 63%, \( p = 0.02 \)) at 28 days. There were no differences of outcomes between steroid and placebo groups in the corticotropin responders. Although this trial was criticized on both methodological and clinical grounds, a subsequent meta-analysis (Fig.
190.5) showed that a 5- to 7-day course of physiologic hydrocortisone doses increased survival for patients with vasopressor-dependent septic shock [83].

In a follow-up study (CORTICUS), 499 patients with septic shock who remained hypotensive after fluid and vasopressor resuscitation were randomized to receive 50 mg of intravenous hydrocortisone or placebo every 6 hours for 5 days [84]. At 28 days, there was no significant difference in mortality between patients of the two study groups whose plasma cortisol levels did not rise appropriately after administration of corticotropin (39.2% vs. 36.1% in the hydrocortisone and placebo groups, respectively; $p = 0.69$) or between those who had a response to corticotropin (28.8% vs. 28.7%, respectively; $p = 1.00$) (Fig. 190.6). In a meta-analysis of 12 trials investigating prolonged low-dose corticosteroid treatment, 28-day mortality was lower for treated vs. control patients (38% vs. 44%; RR 0.84, 95% CI 0.72 to 0.97, $p = 0.02$) [85]. However, in an observational registry of 17,847 patients who required vasopressor therapy despite fluid resuscitation, the use of low-dose systemic corticosteroids was associated with higher in-hospital mortality (41% vs.
35%; OR 1.18, 95% CI 1.09 to 1.23, p < 0.001) [86]. As discussed previously, correction of relative vasopressin deficiency is an alternative or adjunctive therapeutic strategy in refractory shock.

---

**FIGURE 190.6** Shown are Kaplan–Meier curves for survival at 28 days comparing patients with septic shock who received hydrocortisone versus placebo. There was no difference among patients who did not have a response to a corticotropin test (Panel A), those who had a response to corticotropin (Panel B) and all patients randomized (Panel C).

(From Sprung CL, Annane D, Keh D, et al)

Calcium

The routine use of intravenous calcium has been shown to have no benefit in the setting of cardiac arrest and may be detrimental by causing cellular injury [19]. Indications for acute calcium administration in the hypotensive patient include correction of clinically significant hyperkalemia (e.g., with acute kidney injury) or hypocalcemia (e.g., following multiple blood transfusions) and as an antidote to calcium channel blocker or β-blocker overdose [87,88]. Calcium chloride (100 mg per mL in a 10-mL vial) is usually given as a slow intravenous push of 5 to 10 mL, and may be repeated as needed. Rapid intravenous administration of calcium may cause bradycardia or asystole particularly in patients receiving digoxin. In critically ill patients, ionized calcium rather than total calcium concentration should be followed.
There are few large, randomized, well-controlled studies to guide the pharmacologic management of hypotension. The use of vasopressors and positive inotropes is generally based on data from animal studies and small, often poorly controlled clinical trials. Useful consensus recommendations can be found in the recently revised Advanced Cardiovascular Life Support guidelines [7] and the International Guidelines for Management of Severe Sepsis and Septic Shock updated in 2013 [3].

The selection of the appropriate vasoactive agent can be individualized with attention to the known or suspected underlying cause of hypotension (Table 190.3). However, the clinician is commonly faced with a patient who presents with life-threatening hypotension of unknown etiology. In this setting, it may be necessary to initiate a vasopressor as a temporizing measure even before the adequacy of intravascular volume repletion can be ensured. Consensus guidelines for management of septic shock recommend norepinephrine as a first-line vasopressor agent, with dopamine as an alternative for patients with low risk of tachyarrhythmias or who have bradycardia [3]. Although dopamine in moderate to high doses can provide both positive inotropic and vasopressor effects, atrial or ventricular arrhythmias may be provoked. For severe hypotension in the coronary care unit (systolic blood pressure less than 70 mmHg), a more potent α1-adrenergic agonist such as norepinephrine should be considered. If greater control of heart rate is required, the addition of esmolol may be considered. In an open-label study of 154 patients with septic shock and a heart rate greater than or equal to 90 beats per minute, the addition of esmolol titrated to maintain heart rate between 80 and 94 beats per minute improved stroke volume index and renal function, decreased serum lactate and fluid requirements, and reduced 28-day mortality (49% vs. 81%, adjusted HR 0.39, 95% CI 0.26 to 0.59, p < 0.001) (Fig. 190.7) [89].

<sup>a</sup>Volume resuscitation with intravenous fluids and/or blood products recommended.
<sup>b</sup>For obstetric patients.

For the hypotensive patient with significant cardiac pump dysfunction...
(cardiac index less than 2.2 L/min/m² associated with end-organ dysfunction), dobutamine should be considered. Milrinone is often not tolerated in this situation owing to its vasodilating properties. With frank cardiogenic shock and concomitant vasoplegia, a drug with pressor action is usually needed. In this setting, vasopressin and norepinephrine can be used in combination with dobutamine. Rarely, epinephrine may be required. In patients with septic shock and related myocardial dysfunction, dobutamine up to 15 μg/kg/min or higher can be added for additional inotropic support [3]. Although dopamine is also often considered for this clinical situation owing to its combined inotropic and pressor properties, there has been concern that mortality may be increased when compared to norepinephrine based on a subgroup of patients with cardiogenic shock in the SOAP II trial (Fig. 190.3B) [23].

Current experience with phenylephrine is insufficient to assess its efficacy relative to older agents, although its peripheral selectivity and lack of positive chronotropic effects make it a theoretically useful agent for cases in which tachycardia, tachyarrhythmias, or both limit the use of other drugs. Epinephrine is the least selective of the catecholamines and is occasionally added for refractory septic shock. Vasopressin is emerging as an alternative to adrenergic agents, but its use for hypotension may be limited to patients with hemodynamic collapse that is resistant to adequate fluid resuscitation and high-dose conventional vasopressors. For patients with vasoplegic shock refractory to multiple pressors, including those status post cardiopulmonary bypass, a trial of methylene blue should be considered [68–70].
For the volume-resuscitated patient with persistent hypotension, vasoactive medications are administered with the goal of improving arterial pressure while avoiding myocardial ischemia, arrhythmias, and excess vasoconstriction. Although a mean arterial blood pressure of greater than 60 mmHg is usually adequate to maintain autoregulatory blood flow to vital organs [90], some patients may require considerably higher pressures [91]. Therefore, it is essential to use other indicators of global and regional perfusion in addition to the mean arterial pressure to guide therapy. Altered mental status, oliguria, and cool skin are important clinical signs of poor perfusion, but are somewhat nonspecific. The clinical use of mixed venous oxygen saturation and serum lactate level, as well as intramucosal pH monitoring by gastric tonometry remains unproven [3]. Although some clinicians have advocated achieving “supranormal” levels of oxygen delivery in the treatment of critically ill patients, this approach is controversial [92], and adverse effects of hyperoxia have been demonstrated on coronary blood flow and myocardial function among patients with coronary artery disease [93] and heart failure [94], respectively. A meta-analysis in critically ill patients found that various approaches to hemodynamic optimization reduced mortality when patients were treated early to achieve hemodynamic goals before the development of organ failure and when therapy produced differences of oxygen delivery [95].

Vasopressors and positive inotropes are powerful drugs with considerable potential for toxicity. Diligent monitoring and careful adjustment of medications based on changes in clinical status are essential. Patients should be treated in an intensive care setting with continuous monitoring of cardiac rhythm, urine output, and arterial oxygenation. Fluid resuscitation and careful attention to intravascular volume are paramount, because up to 50% of patients with hypotension related to sepsis may stabilize with fluids alone [3]. Moreover, the administration of vasopressors to intravascularly depleted patients can worsen end-organ perfusion. The routine use of pulmonary artery catheters in this setting remains unproven, because overaggressive treatment may increase the risk of adverse events [96]. For patients who do not respond adequately to initial fluid boluses and brief infusion of vasopressors, bedside echocardiography or invasive hemodynamic monitoring may help to optimize cardiac filling pressures and performance [97-99]. Intra-arterial cannulation and direct monitoring of blood pressure is suggested during prolonged vasopressor use. Drugs should be administered through central venous catheters via volumetric
infusion pumps that deliver precise flow rates. In the event of vasopressor extravasation, an $\alpha_1$-adrenergic antagonist (e.g., phentolamine, 5 to 10 mg, diluted in 10 to 15 mL of saline) can be infiltrated into the area to limit local vasoconstriction and tissue necrosis.

With few exceptions, the drugs discussed in this chapter are short-acting agents with rapid onset and offset of action. They are generally initiated without a bolus and can be titrated frequently. Abrupt lowering or discontinuation of vasoactive drugs should be avoided to prevent rebound hypotension. Common dose ranges are provided in Table 190.1, but there may be a considerable variation of the dose required to restore adequate hemodynamics. Furthermore, an individual patient’s response to an agent may diminish with time owing to several mechanisms, including adrenergic receptor desensitization [100,101].

Critically ill patients in the ICU are generally treated with multiple drugs in addition to vasoactive agents (e.g., other cardiovascular medications and antibiotics). Careful attention should be paid to potential drug–drug interactions, because they can significantly alter the response to a given sympathomimetic amine. For example, prior or current treatment with a $\beta$-adrenergic antagonist can cause resistance to the action of dobutamine or other $\beta$-adrenergic agonists. The administration of less-selective drugs (e.g., norepinephrine) to a patient receiving chronic $\beta$-blockade can result in unopposed $\alpha$-adrenergic stimulation. Another well-described interaction is the exaggerated response to some catecholamines among individuals taking monoamine oxidase inhibitors. The starting dose for these patients should be less than 10% of the usual dose [1]. ICU rounding with a dedicated ICU pharmacist is recommended.

CONSEQUENCES OF ISCHEMIA

Within 8 to 10 seconds after occlusion of an epicardial coronary artery, myocardial oxygen supply is exhausted, resulting in a shift from aerobic to anaerobic metabolism [1]. With continued ischemia, high-energy phosphates become depleted, while hydrogen ions, lactate, and other metabolic byproducts accumulate. Disruption of the cell membrane allows protein leakage out of the cell, producing serologic evidence of myocyte injury. The onset and extent of irreversible tissue injury depend on many factors, such as myocardial oxygen consumption, ischemic preconditioning, and collateral blood flow. In the absence of collateral vessels, irreversible injury begins after 20 minutes of coronary occlusion. The benefits of reperfusion diminish with time, with salvage of only 10% of potentially viable myocardium at 180 minutes of ischemia [2].

Patency of the epicardial vessel does not necessarily indicate adequate perfusion at the microvascular level. The “no-reflow” phenomenon, indicating microvascular obstruction, has an incidence between 5% and 50% after primary percutaneous coronary intervention (PCI) for ST-segment elevation myocardial infarction (STEMI) depending on the imaging technique employed. Several mechanisms appear to be responsible for microvascular obstruction, including distal embolization, endothelial dysfunction, and external compression of vessels from interstitial and myocyte edema [3,4]. To date, a wide range of mechanical and pharmacologic strategies have been studied to reduce microvascular obstruction, with variable effects. Although early restoration of flow is necessary for myocardial survival, reperfusion also leads to injury...
through oxidative stress and impaired calcium homeostasis [5]. In addition, an intense inflammatory response is activated to clear the infarcted area of debris and prepare for later phases of healing [6].

Ischemia and reperfusion may be followed by a prolonged period of contractile dysfunction known as myocardial stunning. Importantly, the dysfunction associated with stunning is completely reversible. By definition, myocardial perfusion must be restored to normal or near normal to distinguish stunning from myocardial dysfunction due to continued ischemia (hibernation). In general, the myocardium is stunned for a period longer than that of the ischemic insult, often requiring hours to days to regain function [5]. Stunning is observed in clinical scenarios of ischemia–reperfusion, whether global, as with cardioplegia during cardiac surgery or transplant harvest, or regional, as with acute coronary syndromes. Stunning from repeated episodes of demand ischemia may lead to chronic left ventricular (LV) dysfunction. Stunning is clinically important to recognize: since dysfunction may be fully reversible, continued hemodynamic and/or mechanical support may be indicated until ventricular function has recovered. In addition, stunning has implications for the timing of evaluation of LV function to guide therapeutic decisions after myocardial infarction (MI). For example, LV ejection fraction assessment for implantable cardiac defibrillator implantation is generally deferred for at least 1 month following MI.
Approximately 5% to 8% of patients with STEMI and 2.5% of those with NSTEMI (non-ST–segment elevation myocardial infarction) develop cardiogenic shock (CS), the leading cause of death among patients hospitalized with MI. CS is a clinical condition of inadequate end-organ perfusion due to cardiac dysfunction. Hemodynamic parameters of CS include persistent hypotension (systolic blood pressure [SBP] 80 to 90 mm Hg or mean arterial pressure [MAP] 30 mm Hg lower than baseline) with severe reduction in cardiac index (1.8 L/min/m² without support or 2.0 to 2.2 L/min/m² with support) and adequate or elevated filling pressure (LV end-diastolic pressure > 18 mm Hg or right ventricular [RV] end-diastolic pressure > 10 to 15 mm Hg). Clinical evidence of systemic hypoperfusion includes altered mental status, cold and clammy skin, and oliguria.

LV dysfunction due to extensive infarction or ischemia is the most common cause of CS after MI. Mechanical complications of MI such as ventricular septal rupture (VSR), papillary muscle rupture (PMR), and free wall rupture (FWR) can also result in CS, albeit less often; the combined incidence of VSR, PMR, and FWR is <1% in contemporary series [7].

The observation of normal to low systemic vascular resistance among many patients with CS suggests an important role for inappropriate vasodilation in CS. Indeed, neurohormonal and cytokine abnormalities consistent with the systemic inflammatory response syndrome (SIRS) have been observed [8]. Despite the growing recognition of SIRS associated with CS, therapies targeting it remain unproven at this time.

The cornerstone of CS treatment is percutaneous or surgical revascularization of the infarct-related artery. In the prospective, multicenter SHOCK trial, over 300 patients were randomized to early (within 6 hours) percutaneous or surgical revascularization or initial medical stabilization with subsequent revascularization (54 hours after randomization) [9,10]. Despite an excess of death in the early revascularization group, likely related to procedural complications, early revascularization improved the secondary outcome in the trial of survival at 6 months and 1 year (46.7% vs. 33.6%; p < 0.03). This benefit persisted at 3 and 6 years [11]. The benefit of revascularization appears similar to
different patient subgroups (patients with diabetes, women, prior MI, and early vs. late shock) and whether revascularization is achieved with PCI or CABG. Consequently, early revascularization with either PCI or CABG is a class I recommendation for CS complicating STEMI or NSTEMI in American and European guidelines [12–15]. In STEMI patients with CS who are not suitable candidates for PCI or CABG, fibrinolytic therapy should be administered in the absence of contraindications [12].

Supportive measures for patients in CS include inotropes, vasopressors, and mechanical circulatory support (MCS). Diuretics or intravenous fluids may be required depending on the intravascular volume status. Commonly used inotropes and vasopressors in CS include dobutamine, dopamine, and norepinephrine. In a randomized trial comparing dopamine and norepinephrine for multiple etiologies of shock, dopamine was associated with increased arrhythmic events (24.1% vs. 12.4%, p < 0.05) and increased 28-day mortality in the predefined subgroup of patients with CS [16]. Routine use of a pulmonary artery catheter (PAC) to guide hemodynamic management of CS has not been specifically studied in adequately sized randomized trials in the post-MI setting and has not been shown to decrease mortality in any randomized trials in other settings [17].

For several decades, the principal mechanical therapy for CS has been the intra-aortic balloon pump (IABP) and it remains the most commonly used form of MCS in CS. More recently, the routine use of IABP for CS has been questioned. The IABP-SHOCK II trial, a prospective multicenter, open-label trial, randomized 600 patients with CS complicating acute MI to IABP versus no IABP [18]. All patients were planned for early revascularization by either PCI or CABG and received guideline-directed medical therapy. There was no difference in the primary efficacy endpoint of 30-day mortality (HR 0.96, 95% CI 0.79 to 1.17, p = 0.69) or in the safety endpoints (major bleeding, stroke, or peripheral ischemic complications). Other parameters of CS, such as serum creatinine or lactate, were not significantly different between the groups. A Cochrane Collaboration meta-analysis of seven studies including IABP-SHOCK II found that IABP may have a beneficial effect on some hemodynamic parameters, but this does not result in a survival benefit [19]. The authors concluded that there is no convincing randomized data to support the use of IABP in MI-related CS. In the 2013 American College of Cardiology Foundation and American Heart Association Guidelines for the management of STEMI, IABP received a
class IIa recommendation (changed from a previous class I recommendation) in patients with CS after MI who do not quickly stabilize with pharmacologic therapy [12].

Newer forms of MCS in adult patients with CS include left ventricular assist devices (LVADs) such as the Impella and TandemHeart. To date, there is a paucity of data comparing LVADs to IABP, and the former is currently given a class IIb recommendation for treatment of refractory CS [12]. A meta-analysis of 100 patients from three randomized trials (two comparing TandemHeart with IABP and one comparing Impella 2.5 with IABP) showed that while LVADs resulted in higher cardiac index (mean difference 0.35 L/min/m², 95% CI 0.09 to 0.61); higher MAP (mean difference 12.8 mm Hg, 95% CI 3.6 to 22.0); and lower PCWP (mean difference 25.3 mm Hg, 95% CI 29.4 to 21.2), there was no improvement in 30-day mortality (RR 1.06, 95% CI 0.68 to 1.66) [20]. In addition, there are no randomized data demonstrating that use of LVADs in CS is associated with decreased mortality compared to standard therapy. Observational data from the Impella-EUROSHOCK Registry demonstrated that Impella insertion is feasible and results in decreased serum lactate [21]. However, 30-day mortality remains high. Decreased lactate as well as faster weaning of inotropes was also reported in a 40-patient, retrospective, single-center study [22]. Data from the American USPella Registry of patients in CS undergoing PCI demonstrated a potential benefit of Impella insertion prior to PCI (survival to discharge 65.1% vs. 40.7% in pre-PCI and post-PCI Impella groups, respectively; OR of in-hospital mortality 0.37, 95% CI 0.19 to 0.72) [23]. The ideal patient selection strategy, MCS device type, and timing of insertion have yet to be determined [24].

Extracorporeal membrane oxygenation (ECMO) is another option for mechanical support in CS; data are limited to retrospective, nonrandomized studies and no mortality benefit has been demonstrated [25,26]. The ideal use of this technology in this setting will require further study.

Despite advances in revascularization, pharmacotherapy and mechanical support, mortality in CS remains high. Registry data from the United States and Europe demonstrate an in-hospital mortality rate of close to 50% [27,28]. Independent predictors of mortality in CS include older age; history of hypertension, MI, or heart failure; lower blood pressure and worse renal function on presentation; failed reperfusion; and low LV ejection fraction [11,27,29,30].
Right ventricular infarction (RVI) has long been recognized for its distinct clinical and hemodynamic features. Most cases of RVI are caused by proximal occlusion of a dominant right coronary artery (RCA) and RVI may complicate 50% of inferior MI (IMI). Very rarely, the left anterior descending (LAD) artery may be the culprit vessel. RVI causes RV hypokinesis which leads to decreased LV preload and decreased cardiac output (CO). In addition, acute RV dilation in the face of the restraining effects of the pericardium leads to elevated intrapericardial pressure and leftward shifting of the interventricular septum, further compromises LV filling and CO [31].

RV anatomy and physiology are distinct from those of the LV and provide a more favorable oxygen supply to demand profile. In many instances, the RV myocardium may actually be stunned or hibernating and not infarcted. In one cardiac magnetic resonance (CMR) study, RV edema and late gadolinium enhancement (LGE) were relatively common early after MI (51% and 31%, respectively) [32]. At 4-month follow-up, the frequency and extent of LGE were markedly reduced, suggesting limited permanent myocardial damage. In fact, some authors would even consider the term RVI a misnomer and that chronic right heart failure secondary to MI is rare [31].

Early recognition of RVI is crucial because of its implications for management and prognosis. Clinical manifestations of RVI include hypotension in the setting of clear lungs and elevated jugular venous pressure, although the latter may not be evident if the patient is relatively hypovolemic. Conversely, a volume-depleted patient may exhibit sensitivity to preload reduction, such as with the use of nitrates or diuretics. Evidence of interventricular dependence, such as Kussmaul sign (distension of jugular veins during inspiration), may also be present. However, the physical examination is not sensitive for the diagnosis of RVI.

Electrocardiogram (ECG) indicators of RVI include ST-segment elevation in lead III greater than II, ST-segment elevation in lead V1, and >1 mm ST-segment elevation in right-sided precordial lead V4R, the latter being most predictive. These ECG abnormalities may resolve quickly (50% within 10 hours), underscoring the importance of obtaining a right-sided ECG on presentation for all patients with IMI. RVI is also associated with bradyarrhythmias (sinoatrial or atrioventricular [AV] block) and tachyarrhythmias (atrial fibrillation and ventricular tachyarrhythmias). Echocardiography may reveal RV dilation, RV and inferior LV hypokinesis, and paradoxical septal motion. It may also
demonstrate complications of RVI such as RV mural thrombus and pulmonary embolism; right-to-left shunting across a patent foramen ovale; and severe tricuspid regurgitation from acute RV and tricuspid annular dilation or from primary papillary muscle ischemia or rupture. Two small studies have demonstrated that CMR has superior sensitivity to detect RVI compared to physical examination, ECG, and echocardiography [33,34]. Finally, right heart catheterization demonstrating a right atrial pressure >10 mm Hg or >80% of the PCWP supports the diagnosis of RVI.

Treatment of RVI should emphasize urgent reperfusion. Successful reperfusion is associated with significantly improved RV function and clinical outcomes [35]. Intravenous fluid should be judiciously administered to maintain optimal RV preload; 1 to 2 L of isotonic fluid is a reasonable start. Conversely, preload reducing medications should be avoided. Central venous pressure (CVP) monitoring may be helpful for avoiding RV volume overload (CVP > 10 to 14 mm Hg), which may compromise LV preload via ventricular interdependence. As right atrial contraction is an important contributor to right-sided output, AV sequential pacing for complete heart block or direct-current cardioversion for atrial fibrillation should be considered. Inotropic support may be required but pure α-adrenergic agonists should be avoided because they may increase pulmonary vascular resistance, further compromising RV function.

Mechanical support may be necessary until RV function has recovered. IABP may be useful independent of LV systolic function, with increases in MAP, SBP, and diastolic blood pressure [36]. Percutaneous right ventricular assist devices (RVADs) may also be considered. A retrospective cohort of patients treated with the Tandem-Heart RVAD demonstrated improved MAP, CO, and right atrial pressure [37]. Similarly, the prospective, open-label, nonrandomized RECOVER RIGHT study utilizing the Impella RP demonstrated improved hemodynamics with use of this RVAD [38]. Of note, both studies included multiple etiologies of RV dysfunction. Finally, ECMO has also been used in a limited number of patients with RVI [39].

Hemodynamic instability associated with RVI represents only 5% of cases of CS complicating MI but portends high in-hospital mortality, ranging from 23% to 53% [40,41]. A meta-analysis showed that the presence of RVI more than doubles the relative risk of mortality among patients with acute MI (RR 2.59, 95% CI 2.02 to 3.31) [42]. Despite this high mortality, patients surviving the acute insult generally have a good
prognosis with recovery of RV function [43].
MYOCARDIAL RUPTURE

Myocardial rupture is a rare, but immediately life-threatening complication of MI, occurring 1 to 7 days after MI and accounting for 10% to 15% of deaths. The pathogenesis of rupture depends on timing and whether reperfusion has occurred, with intramural hemorrhage causing rupture in the first 48 hours following fibrinolysis, and coagulation necrosis, inflammation, and myocardial disintegration occurring over 3 to 5 days in the absence of reperfusion. In the National Registry of Myocardial Infarction, older age, female gender, and fibrinolysis were independent predictors of myocardial rupture [44].

Myocardial rupture may occur despite a limited infarct area and relatively preserved systolic function because of increased shear stress in the necrotic zone and its borders. Rupture is possible at three sites: a PMR, the VSR, or the ventricular FWR. The specific presentations and sequelae depend on the location of the defect(s) (Table 191.1), but in all cases, prompt diagnosis and management, with expertise from critical care, imaging, interventional and surgical specialities, are critical to prevent irreversible end-organ malperfusion.

**Physical findings**

| Harsh holosystolic murmur, thrill, accentuated $S_2$, $S_3$, pulmonary edema, RV, and LV failure, cardiogenic shock |
| Jugular venous distention, pulsus paradoxus, electromechanical dissociation, and cardiogenic shock |
| Soft murmur in some cases, no thrill, variable signs of RV overload, severe pulmonary edema (may be asymmetric), cardiogenic shock |

**Echocardiographic findings**

| VSR, color Doppler left-to-right shunt across septum, RV dilation, and hypokinesis |
| Myocardial tear $>5$ mm pericardial effusion not always visualized; clot within pericardial space, tamponade |
| Hypercontractile LV, torn papillary muscle or chordae tendineae, flail leaflet, severe MR by color Doppler |

**Cardiac catheterization**

| Oxygen saturation step-up from RA to RV, large V-waves |
| Ventriculography insensitive; equalization of diastolic pressures |
| No oxygen saturation step-up from RA to RV (may occur from RV to PA); large V-waves, high PCWP |

LV, left ventricle; MR, mitral regurgitation; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure; RA, right atrial; RV, right ventricle; VSR, ventricular septal rupture.

---

**Papillary Muscle Rupture**

PMR complicates 0.25% of AMI patients treated with PCI and is the
etiology of CS for 7% of cases [7]. The posteromedial papillary muscle is affected three times more often than the anterolateral papillary muscle as the former has a single vascular supply (RCA or left circumflex artery [LCx], depending on dominance) while the latter has a dual vascular supply (LAD and LCx). Complete or partial rupture of the papillary muscle can lead to varying degrees of mitral regurgitation (MR). PMR can occur despite a limited territory of infarction and it is not uncommon to observe PMR with relatively preserved LV function.

Patients with PMR present with acute dyspnea secondary to pulmonary congestion. Physical examination may reveal a systolic murmur best heard at the apex, diminished air entry and crackles. The murmur may be absent due to equalization of the left atrial and LV pressures. The diagnosis is suggested by the presence of large V-waves in the PCWP tracing, however this finding may also be seen with severe LV dysfunction, VSR, or other etiologies of MR. Indeed, a much more common mechanism of MR following MI is tethering of the mitral leaflet(s) due to ischemia and dysfunction of the papillary muscle and/or underlying LV segments. The diagnosis of PMR is made by echocardiography with visualization of a flail portion of the mitral leaflet or a ruptured papillary muscle head prolapsing into the left atrium, along with color Doppler evidence of MR (Video 191.1), which has a distinct appearance from ischemic MR (Video 191.1). Transesophageal echocardiography (TEE) should be performed if there is inadequate visualization by the transthoracic approach.

Initial stabilization may be accomplished with inotropic agents, afterload reduction as tolerated, and placement of an IABP. However, in-hospital mortality is as high as 80% when medical therapy is used alone and surgical intervention is indicated for patients who are suitable surgical candidates. The use of ECMO or LVAD prior to surgery has been described in a limited number of patients [45,46]. Surgical repair may consist of chordal-sparing mitral valve replacement or, if necrosis is limited, papillary muscle re-implantation with or without ring annuloplasty. Coronary angiography should be performed prior to surgery so that CABG can be performed concomitantly if necessary. Thirty-day mortality ranges from 22.5% to 39.3% with surgery. Mortality is reduced with concomitant CABG whereas low CO, renal failure, complete PMR, and the need for ECMO or intraoperative IABP portend a worse prognosis [47–49]. Percutaneous repair with the MitraClip device has been successfully employed in this setting but data is limited to case reports [50,51]. Long-term survival after surgery ranges from 60% to 80% and is similar to that of matched patients with MI but no PMR [49].

**Ventricular Septal Rupture**
VSR is a rare but devastating complication of transmural MI, typically associated with total occlusion of the infarct-related artery and poor collateral flow. Infarctions from the LAD, dominant RCA, or dominant LCx may all involve branch arteries to the septum. Anterior infarctions are more likely to cause apical defects and inferior or lateral infarctions are more likely to cause basal defects. Complex VSRs, serpiginous lesions with an exit site remote from the entry site, are more frequently noted with IMI. Five to 10% of patients have multiple defects.

Prior to the advent of fibrinolytics and percutaneous reperfusion therapies, VSR occurred in 1% to 2% of patients with acute MI, an average of 3 to 5 days after MI. More contemporary series report an incidence between 0.17% and 0.31% [52]. Despite this decline, mortality remains high (41% to 80%) and essentially unchanged. Risk factors for developing a VSR include advanced age, female sex, chronic kidney disease, and cerebrovascular disease [53]. Positive biomarkers, CS, higher Killip class, and longer time to reperfusion are additional risk factors [7].

VSR causes an abrupt shunting of flow from the LV to the lower pressure RV. Consequently, there is acute volume overload of the right heart and impaired forward CO. The degree of shunting and hemodynamic compromise, which may vary from complete stability to acute shock, depends on the rupture size, the relative resistance of the pulmonary and systemic circulations, and the relative function of the ventricles. Symptoms include chest pain, dyspnea, and altered mental status. Physical examination reveals hypotension with a harsh, pansystolic murmur best heard at the left sternal border, as opposed to at the apex, which would be more suggestive of PMR. A parasternal thrill is present in half of patients. Signs of RV failure including jugular venous distension, a loud pulmonic component of the second heart sound, and lower extremity edema may also be present; a third heart sound may result from LV or RV volume overload. ECG findings include persistent ST-segment elevation and AV nodal or infranodal conduction abnormalities. As the LV fails and systolic pressure decreases, left-to-right shunting decreases. If RV pressures exceed those on the left, right to left shunting occurs, resulting in hypoxemia.

The diagnosis of VSR is most commonly made using echocardiography, which can demonstrate a dropout of the interventricular septum on 2D imaging and flow across the septum on Doppler imaging (Video 191.2). Moreover, echocardiography provides information about LV and RV function. Right heart catheterization demonstrates a step-up in oxygen saturation (>8%) in the RV; increased pulmonary-to-systemic flow ratios ($Q_p/Q_s > 1.4$); and increased right-sided pressures, but is generally not required if echocardiography is readily available. Left ventriculography can also identify a VSR.

Nonsurgical therapies, such as afterload reduction, diuretics, inotropes,
and IABP are purely temporizing and when used alone result in mortality greater than 90%. Surgical repair of a VSR, first performed in 1957, is the definitive treatment. Operative management should also take into account the presence of concomitant CAD and potential revascularization targets, the degree of MR, and the severity of LV and RV dysfunction. Despite surgical repair, mortality remains high: a large cohort from the Society of Thoracic Surgeons database showed a mortality of 54.1% if repair was required within 7 days of MI [54]. Mortality may be significantly reduced if the patient’s clinical status allows surgery to be delayed until myocardial scar tissue has formed [55].

Evidence for use of LVADs, such as the Impella or TandemHeart, and ECMO to stabilize patients until surgery is limited to small case series [56–58], and their role in VSR management is yet to be defined. Percutaneous closure of VSR has been reported with a procedural success rate of 73.6% to 91% [59–61]. In parallel with the surgical experience, the presence of CS and VSR closure in the acute phase are risk factors for mortality. VSR with acute CS is associated with extremely high mortality no matter what the approach. Optimal patient selection and timing of various strategies such as mechanical support and surgical or percutaneous repair remain to be defined.

Free Wall Rupture

LV FWR is the most common type of cardiac rupture with an incidence of 0.52% in patients treated with primary PCI [7]. The temporal pattern of rupture has two peaks: the first within 24 hours and the second between 3 and 5 days after acute MI [62]. As with VSR, FWR can be classified as simple or complex. In addition, risk factors for FWR are similar to those for VSR with successful, early reperfusion and the presence of flow from collateral vessels being protective. The culprit vessel is the LAD or LCx for >80% of cases. Rupture occurs most commonly in the posterolateral free wall close to the papillary muscle insertion.

FWR results in blood rapidly entering the pericardial space and commonly presents as pericardial tamponade, electromechanical dissociation, or sudden cardiac death (Video 191.3). Physical examination is consistent with tamponade and can demonstrate hypotension, a pulsus paradoxus (decrease in SBP >10 mm Hg with inspiration) and elevated JVP. An LV pseudoaneurysm occurs when FWR is contained by adherent pericardium or pericardial adhesions, thus preventing immediate pericardial tamponade and death. Symptoms of contained rupture include recurrent chest pain or pleurisy, emesis without preceding nausea, unexplained restlessness, and syncope. Hypotension may be accompanied by “inappropriate” bradycardia. New ST-segment elevation or T-wave abnormalities may be evident. Pseudoaneurysms can be
diagnosed by echocardiography, contrast or radionuclide ventriculography, or CMR. Diagnostic pericardiocentesis may yield blood; therapeutic pericardiocentesis may destabilize a contained effusion and result in death. Surgical repair is usually necessary, although survival with pericardiocentesis and supportive medical therapy has been reported for selected patients [63].
LEFT VENTRICULAR REMODELING

Acute MI triggers a cascade of molecular and cellular events that leads to changes in LV shape, dimension, and function. This process of remodeling is initially compensatory but becomes maladaptive as increased ventricular wall stress leads to progressive hypertrophy, dilation, spherical distortion, and impairment of contractile function. MR [64] and mechanical dyssynchrony [65,66], if present, further exacerbate ventricular wall stress and adverse remodeling. Because LV remodeling is concordant with clinical outcomes over the natural history of heart failure, its prevention is accepted as a reasonable therapeutic target.

Among patients with MI, infarct size is a major determinant of negative LV remodeling. Thus, timely and effective reperfusion of the occluded artery is central to reduction of infarct size, preservation of ventricular function and long-term prognosis. Various adjunctive cardioprotective strategies for use in the acute setting are under investigation but their clinical impact is uncertain [67].

The renin–angiotensin–aldosterone (RAAS) and sympathetic nervous systems are central mediators of remodeling. Myocyte stretch from increased wall stress stimulates the local production of angiotensin II, which in turn promotes myocyte hypertrophy, fibroblast proliferation, and collagen production. Adrenergic stimulation, in response to myocardial injury and/or hemodynamic compromise, leads to myocardial production of cytokines, such as tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and interleukin-6 (IL-6), that mediate myocyte hypertrophy, apoptosis, and changes in the extracellular matrix. Furthermore, adrenergic stimulation enhances the activity of the RAAS.

Blockade of the RAAS and sympathetic nervous system is the cornerstone of pharmacologic therapy directed at interrupting remodeling and improving long-term outcome. Angiotensin-converting enzyme (ACE) inhibitors have not only beneficial effects on hemodynamics and loading conditions but also direct effects on remodeling, and confer a survival benefit in patients with MI [68–71]. ACE inhibitors thus carry a class I recommendation for patients with STEMI with an anterior location, heart failure or LV ejection fraction <40%, and a class IIa indication for all patients with STEMI, who have no contraindications [12]. Patients who are intolerant of ACE inhibitors appear to derive similar benefit from angiotensin-receptor blockers (ARBs) [72]. Aldosterone blockade for patients without contraindication has also been shown to improve survival in patients with LV dysfunction after MI [73].

β-Blockers reduce myocyte apoptosis, collagen deposition, and
hypertrophy; they reduce myocardial oxygen demand by reducing heart rate and blood pressure; and they directly oppose catecholamine stimulation of myocytes. \(\beta\)-Blockers reduce not only infarct size when administered early after MI \([74]\), but also future remodeling \([75,76]\), and carry a class I recommendation for patients with STEMI in the absence of contraindications \([12]\).

Finally, novel strategies to prevent LV remodeling after MI are under investigation, including regenerative therapies utilizing stem cell and paracrine factors and pharmacologic interventions targeting oxidant stress, inflammatory and matrix-metalloproteinase pathways.

Recommendations for the management of the mechanical complications of MI based on randomized controlled trials are summarized in Table 191.2.

### TABLE 191.2 Summary of Recommendations Based on Randomized Controlled Clinical Trials

- Cardiogenic shock: Early revascularization by PCI or CABG in suitable patients reduces mortality \([10,11]\).
- Remodeling: ACE inhibition, angiotensin-receptor blockade and aldosterone blockade in patients with evidence of LV dysfunction after MI attenuates LV remodeling and improves survival \([68–73]\).
- Remodeling: \(\beta\)-blockade in patients after MI attenuates LV remodeling and improves survival \([74–76]\).

ACE, angiotensin-converting enzyme; CABG, coronary artery bypass graft; LV, left ventricular; MI, myocardial infarction; PCI, percutaneous coronary intervention.

**Video 191.1** Papillary muscle rupture complicating inferior MI as seen by trans-esophageal echocardiography. **A.** The ruptured papillary muscle is seen prolapsing into the left atrium during systole, associated with flail motion of the anterior mitral leaflet. **B.** Color Doppler imaging demonstrates severe, eccentric mitral regurgitation. **C.** A short-axis view of the left ventricle showing only the anterolateral papillary muscle.

**Video 191.2** Ventricular septal rupture complicating a late-presentation anterior MI as seen by trans-thoracic echocardiography. **A.** The rupture is clearly seen in the mid-septum in this apical 4-chamber view. The right ventricle is noted to be dilated and akinetic due to acute volume overload. **B.** Color Doppler imaging demonstrates bi-directional flow across the interventricular septum.
Video 191.3 Trans-esophageal echocardiography in a patient with late-presentation of inferolateral MI. **A.** In this long-axis view, the inferolateral wall is akinetic, resulting in severe tethering of the posterior mitral leaflet. **B.** Color Doppler imaging demonstrates severe ischemic mitral regurgitation. **C.** A new small pericardial effusion is noted during the echocardiogram. **D.** The effusion increases quickly over the next few minutes leading to compression of the right ventricle and pericardial tamponade. Note the spontaneous echo contrast in the left heart reflecting stasis from low cardiac output. A free wall rupture was suspected and the patient immediately underwent surgical exploration and repair of a lateral wall rupture, as well as coronary artery bypass and mitral valve replacement.
REFERENCES

The incidence of valvular heart disease continues to rise owing to the increasing longevity of the population and, thus, remains a source of significant morbidity and mortality [1]. More than 5 million Americans are living with valvular heart disease, and nearly 100,000 undergo valve surgery each year [2]. Patients with native or prosthetic valvular heart disease constitute a significant proportion of intensive care unit (ICU) admissions. Many patients will come to medical attention during an acute illness that triggers an abrupt change of cardiac physiology. Although stabilization with medical management is possible for patients with mild-to-moderate disease, surgery may be urgently required when severe valvular heart disease is present. A prompt diagnosis requires a high index of suspicion as defined by the clinical history and a careful physical examination [3]. Timely cardiac imaging with transthoracic echocardiography (TTE) can define valve anatomy and lesion severity. Transesophageal echocardiography (TEE) may be required in selected circumstances for better visualization of valve structures and characterization of the hemodynamics. The need for an invasive hemodynamic assessment may follow. An early collaboration among intensivists, cardiologists, and cardiac surgeons is critical for optimizing patient outcomes. This chapter highlights an integrated approach to the diagnosis and treatment of the native and prosthetic valve disease most commonly encountered in an ICU setting.

AORTIC STENOSIS

Aortic stenosis (AS) is a progressive disease for which there is no medical treatment. The ICU management of patients with AS may be quite challenging, particularly in the setting of concomitant medical illness. Characterizing the severity of stenosis is critical for determining the timing of surgical intervention and requires a careful history, physical
examination, and initial imaging with TTE (Fig. 192.1)

**FIGURE 192.1** Transthoracic echocardiogram of severe valvular aortic stenosis. A: Transthoracic echocardiogram parasternal long axis view of the aortic valve during systole. Aortic valve leaflets are thickened with severely restricted motion consistent with severe aortic stenosis. Solid arrowheads point out minimal leaflet excursion consistent with stenosis. Ao, aortic root; AV, aortic valve, LVOT, left ventricular outflow track. B: Transaortic continuous wave Doppler jet from the apical five chamber view. Peak transaortic velocity is 4.68 m per second, producing an estimated peak transaortic gradient of 87 mm Hg.
Etiology

AS accounts for one-quarter of all chronic valvular heart disease, with approximately 80% of symptomatic cases occurring in adult males. Common etiologies of valvular AS include age-related calcific degeneration, stenosis of a congenitally bicuspid valve, and rheumatic heart disease. Age-related degenerative calcific AS is the most common cause of AS among adults in the USA, but bicuspid disease has become the most common etiology noted at time of isolated aortic valve replacement (AVR) surgery for AS [4]. Over 30% of adults >65 years of age exhibit aortic valve sclerosis, whereas 2% have more severe valvular stenosis. The valve cusps are focally thickened or calcified in aortic sclerosis, with production of a systolic ejection murmur, but without significant outflow obstruction (peak jet velocity <2.5 m per second). Recent studies suggest that calcific AS is the end result of an active disease process rather than the inevitable consequence of aging [5,6]. There may also be a genetic predisposition to calcific degeneration of trileaflet valves [7]. The histologic appearance of a sclerotic valve is similar to atherosclerosis, with inflammation, calcification, and thickening, though the pathologic processes of valve fibrosis/calcification and atherosclerosis are not identical [8]. Both calcific AS and aortic sclerosis appear to be a marker for coronary heart disease events [9].

Older age, male sex, smoking, diabetes mellitus, hypertension, chronic kidney disease, and hypercholesterolemia are all risk factors for calcific AS. High-dose lipid-lowering therapy has not been shown to retard the progression of AS in randomized trials [10,11].

Congenitally bicuspid aortic valves are present in 1% to 2% of the population, with a 4 to 1 male predominance, and seldom result in serious narrowing of the aortic orifice in childhood [12]. Abnormal valve architecture makes the two cusps susceptible to hemodynamic stresses, ultimately leading to thickening, calcification, and fusion of leaflets; and narrowing of the orifice [13] AS develops earlier in bicuspid valves, usually in the fifth or sixth decades, compared with trileaflet aortic valves, which usually do not develop calcific AS until the sixth or seventh decade of life [14]. Bicuspid aortic valves are also associated with aortic regurgitation, aortic root dilatation, and aortic coarctation (Fig. 192.2). Up to 25% to 40% of patients with bicuspid aortic valve will have a root or ascending aortic aneurysm unrelated to the severity of the valve lesion. Patients with bicuspid aortic valves are susceptible to aortic dissection [15]. Cystic medial degeneration similar to that seen in Marfan syndrome is responsible for aneurysm development with a bicuspid aortic valve [16].
Rheumatic disease may affect the aortic leaflets, leading to commissural fusion, fibrosis, and calcification, with narrowing of the valve orifice. Rheumatic AS is almost always accompanied by involvement of the mitral valve and concomitant aortic regurgitation. Radiation-induced AS as a sequela of cancer radiotherapy often occurs in conjunction with proximal coronary artery disease. Rare causes of valvular AS include Paget’s disease of the bone; rheumatoid arthritis; and ochronosis. By the time AS becomes severe, dense calcification and thickening may make it difficult to determine the underlying valve architecture and the precise etiology of AS.

In addition to valvular AS, other causes of left ventricular (LV) outflow obstruction include hypertrophic obstructive cardiomyopathy (HOCM); discrete congenital subvalvular AS resulting from a fibromuscular membrane; and supravalvular AS. The various causes of LV outflow obstruction can be differentiated by careful physical examination and TTE.

Pathophysiology

Obstruction to LV outflow produces a pressure gradient between the LV and the aorta (Fig. 192.3). The ventricle responds to this pressure overload by slowly developing concentric hypertrophy, which is initially adaptive because it reduces wall stress. The law of Laplace states that wall stress is directly proportional to the product of LV pressure and radius, and inversely proportional to LV wall thickness. Compensatory hypertrophy may accommodate a large pressure gradient for years before it becomes maladaptive and LV function declines, with chamber dilatation and reduced cardiac output [17]. In the setting of AS with preserved ejection fraction, cardiac output may be normal at rest but fail to rise appropriately with exercise. Coronary flow reserve may be reduced because of the increased oxygen demand of the hypertrophied LV; the
increased transmural pressure gradient; the decreased capillary density, and the increased distance across the hypertrophied LV that blood must travel to reach the subendocardium [18]. Taken together, these factors can contribute to subendocardial ischemia even in the absence of epicardial coronary artery disease [19]. The loss of appropriately timed atrial contraction, such as that occurs with atrial fibrillation (AF), may cause rapid progression of symptoms because of the reliance on atrial systole to fill the stiff, hypertrophied LV.

**FIGURE 192.3**  Pathophysiology of AS. LV outflow obstruction results in a gradual increase in LV systolic pressure, an increase in LVET, an increase in LV diastolic pressure, and a decrease in mean Ao pressure. Increased LV systolic pressure results in compensatory LVH, which may lead to LV dysfunction and failure. Increased LV systolic pressure, LVH, and LVET increase myocardial oxygen (O$_2$) consumption. Increased LVET results in a decrease in LV diastolic time (myocardial perfusion time), and increased LV diastolic pressure and decreased Ao diastolic pressure decrease coronary perfusion pressure, thereby decreasing myocardial supply. Increased myocardial O$_2$ consumption and decreased myocardial O$_2$ supply produce myocardial ischemia, which further compromises LV function. AS, aortic stenosis; LV, left
No single parameter of valve structure or function is sufficient to define the severity of AS. Integration of the clinical history, physical examination, and TTE is required to place the lesion in context [20]. The physical examination of AS in the ICU may be particularly challenging, contributing to the greater importance of timely TTE. Echocardiographic criteria for severe AS among patients with normal underlying LV function include calcified leaflets with reduced excursion, maximal transaortic jet velocity of >4 m per second, mean gradient transaortic gradient of >40 mm Hg or an effective aortic valve orifice of <1 cm² (Table 192.1). When there is underlying LV systolic dysfunction, severe AS may be present despite low transaortic velocities, reduced flow, and low mean gradient (low-flow, low-gradient severe AS with low ejection fraction). Such patients are at particularly high risk for complications and require further evaluation (usually with dobutamine stress echocardiography) to determine if true valvular AS is present, or whether the reduced valve area relates to an underlying cardiomyopathy (pseudo-severe AS) [21]. Elderly, hypertensive patients might exhibit severe AS (valve area index <0.6/cm²/m²) with reduced flow (stroke volume index < 35 mL/m²) despite a normal ejection fraction. Such “paradoxical” low-flow, low-gradient severe AS requires aggressive treatment of systemic hypertension and reevaluation with TTE [22].

Clinical Presentation
History

The cardinal symptoms of AS are dyspnea, angina, and syncope [23]. Exertional dyspnea is typically the first reported symptom and reflects an elevation in LV end-diastolic pressure transmitted to the pulmonary venous circulation. Some patients, particularly the elderly, may report generalized fatigue and weakness rather than dyspnea. Angina occurs in two-thirds of patients with AS and is similar to that reported by patients with flow-limiting coronary atherosclerosis [24]. Syncope is effort related and caused by cerebral hypoperfusion from a drop of mean arterial pressure produced by the combination of peripheral vasodilatation in the presence of a fixed cardiac output or an inappropriate baroreceptor reflex. Severe AS is also rarely associated with acquired von Willebrand’s disease related to sheering of von Willebrand multimers passing through the stenotic orifice [25]. As a result, gastrointestinal bleeding, epistaxis, or ecchymoses may be present among patients with severe AS [25].

Most patients with AS have gradually increasing LV obstruction over many years, producing a long latent phase. During this clinically silent period, there is a very low risk of sudden death (<1% per year) [26]. The rate of AS progression is variable, with an average increase in mean gradient of 7 mm Hg and reduction of valve area of 0.1 cm² per year [27]. Symptoms from valvular AS are rare until the valve orifice has narrowed to approximately <1 cm². The onset of symptoms is a critical turning point in the natural history of the disease, usually indicates severe AS, and heralds the need for surgical evaluation and treatment because of the markedly reduced survival with symptomatic severe AS [23] (Fig. 192.4). An abrupt change in the natural history of AS may occur with AF, endocarditis, or myocardial infarction, each of which may trigger acute decompensation [28].
The hallmark of AS is a carotid arterial pulse that rises slowly to a delayed peak, known as *pulsus parvus et tardus*. Among the elderly, stiffened carotid arterial walls may mask this finding. Similarly, patients with AS and concomitant aortic regurgitation may have preservation of the arterial pulsation caused by an elevated stroke volume. The LV apical impulse may be displaced laterally with a sustained contour caused by LV hypertrophy and prolonged systolic ejection in the face of valve obstruction.

The murmur of AS is a systolic ejection murmur commencing shortly after S1; rising in intensity with a peak in mid ejection; and then ending just before aortic valve closure. It is characteristically low-pitched; harsh or rasping in character; and best heard at the base of the heart in the second right intercostal space. The AS murmur is transmitted upward along the carotid arteries, though may sometimes be transmitted to the apex where it may be confused with the murmur of mitral regurgitation (Gallavardin phenomenon). The murmur of AS is diminished with the Valsalva maneuver and standing, in contrast to the murmur of LV outflow tract obstruction in hypertrophic cardiomyopathy, which gets louder with these maneuvers. Often, S2 becomes paradoxically split in severe AS because of prolonged LV ejection. An S4 is audible at the apex and reflects LV hypertrophy with an elevated LV end-diastolic pressure. An S3 generally occurs late in the course of AS when LV dilatation is present. Murmur intensity does not necessarily correspond to AS...
severity. The best predictors of AS severity on physical exam are a late peak to the systolic murmur, a single S2 (absent aortic valve closure sound) and pulsus parvus et tardus. Among patients with heart failure and a low cardiac output, the clinical examination may be misleadingly unimpressive.

Investigations

Electrocardiography

Most patients with severe AS will have electrocardiography (ECG) evidence of LVH. Left atrial (LA) enlargement is common. Nonspecific ST and T wave abnormalities may be seen or evidence of LV strain may be apparent. Rarely, atrioventricular conduction defects may develop because of extension of perivalvular calcium into the adjacent conduction system. This finding is more common after AVR. There is poor correlation between ECG findings and AS severity. The presence of left bundle branch block may equate with a higher risk of advanced AV block after valve replacement (either surgical or transcatheter).

Chest Radiography

The chest radiograph may be normal with severe AS. There may be “post-stenotic” dilation of the ascending aorta, or a widened mediastinum if aortic aneurysmal dilatation is present in patients with a bicuspid aortic valve. LV chamber size is usually normal, though aortic valve calcification may be seen, especially on the lateral film. Valvular calcium deposits can be visualized using fluoroscopy during cardiac catheterization, chest CT, or TTE. A normal chest X-ray does not exclude severe AS. In the later stages of AS, the LV dilates, leading to a widened cardiac silhouette, often accompanied by pulmonary congestion.

Echocardiography

TTE with Doppler is indicated for assessing the severity of AS. TTE visualized aortic valve structure, including the number of cusps; the degree of calcification; leaflet excursion; annular size; and supravalvular anatomy. Eccentric valve cusps are characteristic of congenitally bicuspid aortic valves and are often accompanied by aneurysmal enlargement of the root or ascending aorta. TTE is also useful for identifying coexisting
valvular disease; differentiating valvular AS from other forms of LV outflow tract obstruction; checking for secondary pulmonary hypertension; and evaluating underlying biventricular function. The peak transvalvular jet velocity on continuous wave Doppler is critical for assessing AS severity. Peak and mean transvalvular gradients are derived from the jet velocity using the modified Bernoulli equation, and the aortic valve area is estimated from the continuity equation. The dimensionless index, which is the ratio of the LV outflow tract velocity time integral (VTI) to aortic VTI, can also be used to estimate AS severity when measurement of LV outflow tract diameter is difficult because of extensive calcification. A dimensionless index <0.25 is consistent with severe AS [20]. Advanced TTE techniques may be required to evaluate patients with suspected low-flow, low-gradient severe AS. Transesophageal echocardiography can be used when TTE images are inadequate to assess the severity of AS.

Cardiac Catheterization

Noninvasive assessment with TTE is now standard, but catheterization may be helpful when there is a discrepancy between the clinical and echocardiographic findings. Calculation of aortic valve area by invasive hemodynamic assessment requires accurate assessment of the transvalvular flow and mean transvalvular pressure gradient to calculate effective orifice area using the Gorlin formula [29]. Concerns have been raised about the risk of cerebral embolization during attempts to cross the aortic valve and directly measure the transaortic gradient. Angiography is indicated to detect coronary artery disease for patients >45 years old who are being considered for operative treatment of severe AS [30]. Coronary CT angiography is now performed more often for this indication.

Special Case: Low-Flow/Low-Gradient Aortic Stenosis

The appropriate diagnosis and management of patients with AS and a depressed ejection fraction (EF) can be vexing. Patients with anatomically severe AS and reduced EF (<40%) often have a relatively low pressure gradient (<30 mm Hg) because of a weakened ventricle. The true severity of AS can be difficult to determine when the cardiac output and transaortic gradient are low. If the ventricle itself is diseased and unable to generate sufficient systolic force to open the leaflets adequately, a reduced aortic valve area may be present at rest, overestimating AS severity. This condition is known as pseudo-severe AS [31]. In such cases, LV dysfunction is the predominant pathology and may be caused by prior MI or a primary cardiomyopathy. Patients with either true severe AS with
reduced EF or pseudo-severe AS have a low-flow state with low trans-aortic gradients contributing to calculated aortic valve areas <1 cm². Pseudo-severe AS patients must be distinguished from those with true severe AS and poor LV function, since patients with true severe AS and flow reserve will usually benefit from valve surgery, whereas patients with pseudo-severe AS are not operative candidates [32–34].

Dobutamine stress echocardiography has a well-defined diagnostic role in this setting [35] (Fig. 192.5). The inotropic effects of low-dose dobutamine will increase transvalvular flow in patients with flow reserve [36]. Flow reserve is defined as an increase in stroke volume with inotropic infusion of >20%. Dobutamine infusion, particularly at doses <20 μg/kg/min, is generally well tolerated, but should only be performed at experienced centers with a cardiologist in attendance. In patients with genuine severe AS and LV dysfunction, dobutamine will increase cardiac output and mean transvalvular gradient but calculated aortic valve area will remain low (<1 cm²). Patients with pseudo-severe AS will have an increase in aortic valve area into a range no longer considered severe (>1.2 cm²) with little change in transvalvular gradient. Some patients will not have any flow response to dobutamine, signaling a poor prognosis [37]. Surgery is indicated in true severe AS with flow reserve after dobutamine challenge, and generally contraindicated for patients with pseudo-severe AS or those without contractile reserve [30]. Patients with low-flow, low-gradient AS with reduced EF undergoing AVR have a significantly higher perioperative and long-term mortality if multivessel coronary artery disease is also present [33,38]. The evaluation of patients with low-flow, low-gradient severe AS and preserved EF can also be challenging and requires input from an imaging and valve disease expert.
Intensive Care Unit Management

AVR is the preferred treatment strategy for patients with symptomatic severe AS and for asymptomatic patients with severe AS who have a reduced ejection fraction (<50%). In contrast, surgery may be postponed for patients with severe, asymptomatic AS and normal LV function, as these patients may do well for years [39]. AVR is also indicated for patients with moderate AS who require other cardiac surgery, such as
coronary artery bypass grafting (CABG) or aortic aneurysm repair. Patients with severe AS and cardiogenic shock may have percutaneous aortic balloon valvuloplasty (PABV) as a bridge to AVR.

The choice between surgical and transcatheter AVR (SAVR, TAVR) is determined by a multidisciplinary heart valve team that includes cardiologists, interventionalists, imaging specialists, and cardiac surgeons. TAVR is now considered for patients deemed to be a prohibitive, high, or intermediate surgical risk as assessed by the Society for Thoracic Surgeons (STS) Predicted Risk of Mortality (PROM) Score in combination with an assessment for frailty, procedure-specific risk (e.g., a highly calcified ascending aorta), and the presence of vital organ system dysfunction [40]. Many ICU patients have advanced comorbidities that make TAVR an attractive means for treatment of AS.

Medical Management

Medical interventions for severe AS are largely supportive until surgery is feasible. In patients with severe AS with heart failure or cardiogenic shock, management should be guided by invasive hemodynamic monitoring with a pulmonary artery catheter. Diuresis may relieve pulmonary congestion, but caution is advised. For patients in cardiogenic shock, arterial pressure should be supported with inotropes and/or vasopressors until valve surgery can be performed. Vasodilators are generally contraindicated, except for selected patients with depressed ejection fraction [41]. In these select patients with EF <35%; severe AS; and cardiogenic shock accompanied by high systemic vascular resistance, sodium nitroprusside infusion has been shown to modestly improve hemodynamics, and can serve as a bridge to the operating room [42].

Aortic Valve Replacement

AVR is the preferred treatment for severe symptomatic AS [30,43]. Choice of surgical valve prosthesis depends on patient age, anticipated lifespan, and preference for and tolerance of anticoagulation [44]. The perioperative mortality for isolated SAVR ranges from <1% in healthy, younger patients with normal LV systolic function, to 10% or more in elderly patients with coexisting CAD and reduced EF who require concomitant CABG. Age alone is not a contraindication to SAVR. Other factors associated with reduced survival after SAVR include chronic kidney disease, obstructive lung disease, coronary artery disease, reoperation, emergency operation, and age >65 years. The overall 10-year survival for patients with SAVR is approximately 60%.

Balloon aortic valvuloplasty (BAV) is often used instead of an operation for children and young adults with congenital, noncalcific AS. During the
procedure in adults, a balloon in placed across the stenotic aortic valve and inflated to high pressure to fracture adherent calcium and increase effective orifice area [45]. A technically successful procedure can reduce the transaortic valve gradient to a mild degree, but rarely increase valve area to >1 cm². Valvuloplasty is not widely used among adults with severe calcific AS because of high restenosis rates, high frequency of embolic complications (particularly stroke), and the development of aortic regurgitation [46] among adults with acutely decompensated AS, BAV is particularly high risk and has no proven long-term benefits [47]. BAV is almost entirely restricted to its performance during TAVR.

TAVR has an established and growing role in the management of patients with symptomatic severe AS (Fig. 192.6) [40]. The transfemoral access route is strongly preferred whenever possible and is largely dictated by the iliofemoral and aortic anatomy, although other access sites are available (subclavian, transaortic, transapical) (Fig. 192.7). Early and late results have been excellent, but concerns remain about vascular injury, stroke, paravalvular leak, the need for permanent pacing and long-term durability of the prosthesis [48,49]. Transcatheter valve-in-valve implantation is available in many centers for treatment of high-risk patients with structural deterioration of a previously implanted bioprosthesis [50].

**FIGURE 192.6** Five-year outcomes of transcatheter (TAVR, blue) or surgical aortic valve replacement (SAVR, red) in high surgical risks patients with aortic stenosis. Kaplan–Meier analysis of all-cause death in the intention-to-treat analysis of the PARTNER 1 randomized trial

AORTIC REGURGITATION

Acute severe aortic regurgitation (AR) may occur in previously normal or only mildly diseased valves and often results in abrupt hemodynamic decompensation and respiratory compromise requiring ICU admission. Acute valvular regurgitation is a surgical emergency, but accurate diagnosis may be a challenge since exam findings may be subtle and the clinical presentation nonspecific [51]. Patients with acute AR appear gravely ill and have tachycardia, significant dyspnea, and often hypotension. The presentation of acute AR may even be mistaken for other acute conditions like sepsis, pneumonia, or nonvalvular heart failure. In marked contrast, chronic severe AR may be asymptomatic or minimally symptomatic and is rarely encountered in the ICU setting. In cases of acute valvular regurgitation, a high index of suspicion is required, along with timely TTE, and prompt surgical consultation.

Etiology

Most cases of acute severe AR are caused by infective endocarditis (IE), but other causes include aortic dissection and blunt chest trauma. Staphylococci have emerged as the most important causative agents of native valve endocarditis [52,53]. Patients with antecedent aortic valve disease or a congenital bicuspid valve are at increased risk for IE, though organisms like *S. aureus* can infect a normal trileaflet valve [54]. IE is a particular problem among injection drug users, patients with indwelling catheters, and those on hemodialysis. Acute severe AR from IE is the consequence of tissue destruction, leaflet perforation, or bulky vegetations impairing leaflet coaptation [55].

AR is present in up to 65% of patients with Stanford Type A aortic dissection [56]. Ascending aortic dissection may be seen in the setting of Marfan syndrome, bicuspid aortic valve, or in patients following previous CABG or AVR surgery. Retrograde extension of the dissection flap into the annulus may cause prolapse or eversion of the aortic valve leaflets. Type A aortic dissection with AR is a surgical emergency requiring prompt diagnosis and intervention [57]. Aneurysmal enlargement of the aortic root without dissection may also lead to AR. Though AR is usually chronic when produced by aortic root dilatation, an acute-on-chronic decompensation may occur if there is superimposed dissection or abrupt aneurysm enlargement [58]. Important causes of aortic root pathology producing AR include connective tissue disorders (Marfan syndrome and Ehlers–Danlos syndrome) and vasculitis (syphilitic aortitis, giant cell arteritis, or Takayasu’s arteritis). Aortic leaflet tears, perforation, or
detachment producing AR may also follow blunt chest trauma or occur as a complication of BAV for AS [59].

Pathophysiology

Unlike in chronic AR, the LV in acute AR has not had time to develop compensatory eccentric hypertrophy in response to elevated afterload and preload (Fig. 192.8). The nondilated, noncompliant LV receives a significant diastolic volume load from the regurgitant flow, resulting in an abrupt rise in LV end-diastolic pressure. This pressure may in turn be transmitted to the pulmonary bed, resulting in pulmonary edema. Since the LV cannot dilate acutely in response to the volume load, forward stroke volume is decreased, and tachycardia develops to maintain cardiac output. Impaired forward stroke volume leads to decreased systolic pressure and a narrower than anticipated pulse pressure. Patients may present with signs of impending cardiogenic shock. LV diastolic pressure may equilibrate with aortic pressure during the latter half of diastole (diastasis), resulting in attenuation of the AR murmur in the acute setting. The elevation of end-diastolic pressure and tachycardia can increase myocardial oxygen demand and, when coupled with decreased diastolic coronary blood flow owing to lower aortic diastolic pressure, can reduce myocardial perfusion and result in coronary ischemia. Ischemia from AR can be compounded by impaired coronary flow from preexisting atherosclerosis or an aortic dissection flap. In acute severe AR, LV failure and cardiogenic shock develop if surgery is not promptly performed.
Clinical Presentation

History

Acute AR may present with little or no warning. Symptoms like weakness, profound dyspnea, angina, and presyncope are common. Antecedent valve disease, fever, and skin findings may suggest IE. Severe, ripping chest or back pain with hypertension may indicate aortic dissection. Signs of blunt chest trauma may be disarmingly subtle. The natural history of acute severe AR is one of LV failure and death in the absence of rapid intervention. Patients with chronic AR may present acutely with a sudden worsening of their underlying pathology.

Physical Examination
The classic eponymous signs observed in chronic AR are attenuated or absent in acute AR so the degree of AR may be greatly underestimated. Patients are often tachycardic with low or low–normal blood pressure. Pulse pressure may underestimate AR severity in the acute setting. Tachypnea, accessory muscle use, and hypoxemia are worrisome findings, and pulmonary rales are common. LV apical impulse is not displaced unless prior LV dysfunction was present. The first heart sound (S1) is often soft owing to premature closure of the mitral valve from the rapid LV diastolic pressure rise. There is often a low-pitched systolic ejection murmur from increased flow across the aortic valve, whereas the diastolic murmur is of grade 1 or 2 intensity and is of short duration. A pulse deficit or relative decrease may be appreciated in the setting of AR from aortic dissection.

Investigations

Electrocardiography

Sinus tachycardia is often present, though the ECG may be entirely normal in acute severe AR. In contrast, LV hypertrophy is a feature of chronic AR. Nonspecific ST-segment and T-wave abnormalities or signs of LV strain are common. With IE, if there is paravalvular extension of the infection in the region of the atrioventricular node, a heart block of varying degree may be present. In the setting of acute heart failure, supraventricular and ventricular tachycardias may occur.

Chest Radiography

The cardiac silhouette may be normal, unless AR is chronic or there was a preexisting heart disease. Pulmonary edema is common and characterized by cephalization of pulmonary vein flow and Kerley B lines. A widened mediastinum may signify aortic dissection or thoracic aortic aneurysm.

Echocardiography

Urgent TTE is mandated whenever acute AR is suspected. Echocardiography can determine the etiology and hemodynamic severity of AR while providing information about the underlying LV function, aortic size, and coexisting valvular heart disease (Fig. 192.9). Severe AR is characterized by a wide regurgitant jet (vena contracta >7 mm) and holodiastolic flow reversal in the descending thoracic aorta [60,61]. The rapid rise in LV diastolic pressure with acute severe AR produces a short pressure half time (<250 ms) and premature mitral valve closure [62]. CT
angiography has become the preferred imaging test to assess for acute dissection, but TEE may be indicated if the study is nondiagnostic and is crucial for intraoperative planning [63–65].

**FIGURE 192.9** Echocardiographic appearance of severe aortic regurgitation. A: Transthoracic echocardiogram apical four chamber view with severe aortic regurgitation from infective endocarditis. Color Doppler shows ventricular filling from the aorta during diastole. B: Pulse wave Doppler of the descending thoracic aortic reveals holodiastolic flow reversal consistent with severe aortic regurgitation.
**Cardiac Catheterization**

Establishing the hemodynamic severity of AR seldom requires catheterization, which can delay surgery [66]. Younger patients without coronary risk factors may proceed directly to emergency valve replacement without angiography. Patients with Type A dissection should proceed directly to surgical repair.

**Intensive Care Unit Management**

**Medical Management**

Acute severe AR has a high mortality rate. Medical management should not delay urgent or emergent surgery. Congestive heart failure and cardiogenic shock are the principal targets of acute medical therapies. Use of vasodilators, particularly sodium nitroprusside, and diuretics is the mainstay of medical therapy, as the systemic blood pressure allows [67,68]. Inotropes such as dopamine or dobutamine may be used to augment forward cardiac output. Pulmonary edema from acute AR frequently requires intubation and mechanical ventilation. Intra-aortic balloon counterpulsation (IABP) is strictly contraindicated. β-Blockers should only be considered for cases of acute aortic dissection. Antibiotics are indicated for IE, but surgery must not be delayed once heart failure intervenes [30].

**Surgical Treatment**

Surgery is indicated for acute severe AR, unless overwhelming patient comorbidities dictate otherwise. AVR is often performed, but valve repair may be possible for many cases of dissection. Many surgeons favor the use of homograft material for management of aortic valve/root IE, given the low reinfection rates with cadaveric tissue. A composite valve–graft conduit may be used when disease dictates replacement of both the aortic root and the valve [69]. Perioperative risk depends largely on age; preoperative LV function; etiology; and urgency of surgery. Debridement of periaortic abscess or aortic root replacement compounds operative risk.
MITRAL STENOSIS

Widespread use of programs to detect and treat of Group A streptococcal pharyngitis has reduced the incidence of rheumatic fever in the developed world, the leading cause of MS [70]. The burden of rheumatic valve disease in the developing world remains considerable and is a significant cause of premature death. Most cases of rheumatic MS in the USA are seen in patients who have recently emigrated from endemic areas [1]. MS often presents as acute heart failure and, when symptomatic, requires mechanical relief of LV inflow obstruction. ICU management goals include treatment of heart failure, rate control of AF, and preparation for valvotomy or valve replacement surgery.

Etiology

Rheumatic fever produces valvular inflammation and scarring, though nearly half of patients may not recall as history of acute rheumatic fever or chorea. Two-thirds of patients with rheumatic MS are female and 40% of patients with rheumatic valvular disease will have isolated MS [71]. Screening TTE in endemic areas may detect up to 10 times as many cases of rheumatic valve disease compared to clinical screening alone [72]. By contrast, in developed countries, MS is more commonly produced by calcific degeneration of the annulus and mitral leaflets, congenital abnormalities of mitral inflow, or collagen vascular diseases such as lupus or rheumatoid arthritis [73]. Atrial myxoma may mimic MS by causing obstruction to LV inflow. The natural history of MS is often dependent on the patient’s socioeconomic status. In developing countries patients tend to be younger with a more pliable valve, whereas in developed countries patients are older with comorbid conditions [74]. Patients in low- or middle-income countries also have relatively less access to programs for screening; detection; medical and surgical treatment; and anticoagulation management.

Pathophysiology

Rheumatic fever leads to inflammation and scarring of the mitral valve, with fusion of the valve commissures and subvalvular apparatus [70]. Although the initial insult is rheumatic, altered flow patterns may lead to calcification and further valve deformity, leading to a narrow funnel-
shaped valve. Calcific degeneration of acquired mitral valve thickening may also produce MS. The mitral orifice is normally 4 to 6 cm$^2$. MS develops when the area is reduced to <2 cm$^2$ so that an elevated left atrioventricular pressure gradient is required to propel blood across the mitral valve. Severe MS is present when the valve area is <1.5 cm$^2$; the mean gradient is usually >10 mm Hg. An elevated LA pressure leads to pulmonary hypertension (PA pressure >30 mm Hg), exercise intolerance and eventually right-sided heart failure. Adequate transit time is required to allow blood to flow across the stenotic mitral valve during diastole.

Clinical Manifestations

History

MS is a slowly progressive disease with a latent period of up to two decades between the episode of rheumatic carditis and symptom onset. Progression of MS in developing countries is more rapid and may be associated with recurrent episodes of rheumatic fever. The typical patient will have an asymptomatic period with an abnormal physical exam. As MS progresses, lesser stresses precipitate the symptoms, making the patient limited in daily activities; orthopnea and paroxysmal nocturnal dyspnea develop. Pulmonary edema in previously asymptomatic individuals may be triggered by tachyarrhythmias (AF), volume overload, fever, anemia, hyperthyroidism, or pregnancy [75]. Each of these circumstances shortens the diastolic filling period and elevates the LA to LV transvalvular gradient. Development of persistent AF marks a turning point in the patient’s course, with an accelerated rate of symptom progression. Systemic embolization may be the first clue to the presence of MS, irrespective of underlying rhythm [76]. Patients may also suffer from hemoptysis because of shunting between the pulmonary and bronchial veins, leading to rupture. Underappreciated calcific MS may also be identified after failure to wean from mechanical ventilation. The overall 10-year survival with untreated MS is 50% to 60% [77]. Asymptomatic patients have a survival of >80% at 10 years, whereas symptomatic MS led to death within 2 to 5 years in the era before the development of mitral valvotomy [78]. Once pulmonary hypertension develops (>50 mm Hg PA systolic pressure), mean survival is less than 3 years. The common causes of death associated with MS are heart failure, systemic embolism, and infections, including endocarditis.

Physical Examination

MS produces signs of heart failure, including pulmonary rales, peripheral
edema, ascites, an elevated jugular venous pressure, and congestive hepatomegaly. Patients with severe MS may also have a malar flush with pinched and blue facies. The first heart sound (S1) is usually accentuated in the early phases of the disease. The opening snap (OS) of MS is best appreciated in early diastole during expiration near the cardiac apex. The time interval between aortic valve closure (A2) and OS varies inversely with the severity of MS, and the height of the LA pressures. The OS is followed by a low-pitched rumbling diastolic murmur best heard at the apex with the patient in the left lateral decubitus position. Presystolic accentuation of the murmur may be present in sinus rhythm. In general, the duration of the murmur corresponds to the severity of stenosis. If the valve is heavily calcified and immobile, with low cardiac output or AF, it may be relatively “silent” with a soft S1, absent presystolic accentuation, and an inaudible diastolic rumble. Associated valvular lesions, including the murmurs of AR, pulmonic regurgitation (PR), and tricuspid regurgitation (TR), may be present, along with a loud P2 from pulmonary hypertension or a parasternal lift from right ventricle (RV) pressure or volume overload.

Investigations

Electrocardiogram

The ECG in sinus rhythm may reveal LA enlargement, but AF can be present at any stage in the natural history. A vertical QRS axis may be present along with nonspecific ST-segment and T-wave abnormalities. Signs of RV hypertrophy signify advanced disease.

Chest Radiograph

Radiographic changes with MS include LA enlargement; dilation of the main PA and its central branches; RV enlargement; and signs of pulmonary vascular congestion. Interstitial or alveolar edema signifies a marked and often acute elevation of pulmonary capillary wedge pressure.

Echocardiography

Rheumatic MS is characterized by thickened mitral leaflet tips, immobility of the posterior leaflet, and restricted anterior leaflet motion. Calcific MS is marked by dense echogenic deposits throughout the mitral apparatus and turbulent LV diastolic inflow. Direct planimetry to measure valve area may be difficult in heavily calcified valves [79]. Continuous wave Doppler can be used to estimate the LA–LV pressure gradient. Estimates of mitral valve area can be made by the pressure half-
time technique or the continuity equation [80]. Careful assessment of the degree and location of valvular calcification; thickening of the leaflet and subvalvular apparatus; and leaflet mobility can determine suitability for percutaneous mitral balloon valvuloplasty (PMBV) [81]. Routine assessment of chamber dimension and ventricular function should be performed. TEE is required to exclude LA thrombus in patients being considered for PMBV.

Cardiac Catheterization

Catheterization may be necessary to determine the severity of stenosis when noninvasive and clinical data are discordant or as a prelude to PMBV (Fig. 192.10). Cardiac output and mean transvalvular gradient measurements are used to calculate mitral valve area using the Gorlin formula [29].

p. 1849

p. 1850
Intensive Care Unit Management

Medical Therapy

Acute MS typically manifests as pulmonary edema. Reversible precipitants must be identified, such as rapid AF, anemia, sepsis, volume overload, or thyrotoxicosis. Medical therapy is directed at rate control of AF, and alleviation of pulmonary and systemic congestion by loop diuretics. Nodal blocking agents such as β-blockers or non-dihydropyridine calcium-channel blockers are the preferred rate controlling agents and may be administered intravenously [82]. Cardioverson may be required in the acute setting to restore hemodynamic stability, though most patients respond to rate control. Anticoagulation should be initiated promptly. For patients with only mild-to-moderate MS, addressing one or more underlying precipitants will suffice without the need for mechanical intervention. Patients with severe MS have a poor prognosis without intervention, which may consist of PMBV, surgical commissurotomy, or mitral valve replacement (MVR) (Fig. 192.11).
Percutaneous Mitral Balloon Valvuloplasty

PMBV is the preferred treatment for symptomatic (NYHA Class II–IV) patients with isolated severe MS and favorable valve morphology. Unlike BAV, PMBV has achieved durable results. Ideal patients for PMBV are younger (<45 years old), have lower NYHA functional class, and have pliable mitral leaflets [83,84]. PMBV is performed by transseptal puncture, passing a guidewire across the mitral valve, and inflating a balloon (Inoue balloon) across the mitral orifice to split the commissures and widen the stenotic valve [46,85].

Successful PMBV doubles the mitral valve area, reduces mean transmitral gradient by half, and improves symptoms without development of significant mitral regurgitation (MR) [86]. Acute complications of PMBV include severe MR, residual atrial septal defect after transseptal puncture, and, less commonly, LV perforation, cardiac...
tamponade, and systemic emboli [30]. Overall procedural morality is between 0.4% and 3.0% [87]. Patients have excellent event-free survival after PMBV with rates of 80% to 90% over 3 to 7 years when performed by a skilled operator at a high-volume center [88]. Short and intermediate-term outcomes from PMBV are commensurate with open surgical commissurotomy, but with reduced morbidity and at lower cost [89]. There is a significant rate of restenosis after both percutaneous and surgical commissurotomy with most patients requiring a repeat procedure within 10 to 15 years.

**Surgical Treatment**

If the anatomy is unfavorable for PMBV or the procedure is unsuccessful, open surgical valvotomy may be performed, which requires cardiopulmonary bypass [90]. MVR is necessary in patients with MS and significant MR, and those in whom valve anatomy is too distorted to respond to commissurotomy repair alone. MVR is often performed with preservation of the chordal attachments to facilitate LV recovery. A surgical maze procedure of the LA or isolation of the pulmonary veins may also be performed to treat concomitant AF, though success rates are relatively lower for rheumatic MS patients. The average operative risk for MVR is 5%, with an overall 10-year survival in surgical survivors of 70%. Long-term prognosis is influenced by patient age, comorbid conditions, and the presence of concomitant pulmonary hypertension and RV dysfunction [91,92].
MITRAL REGURGITATION

Acute, severe mitral regurgitation (MR) presents with pulmonary edema and hemodynamic compromise because of the lack of time for the cardiopulmonary circuit to adapt to the additional volume load. Examination findings may be subtle and presentation may be mistaken for other acute conditions like pneumonia or nonvalvular decompensated heart failure. A high clinical index of suspicion; timely evaluation by TTE; and prompt referral for surgical consultation are of critical value in the management of this condition [51]. Many patients in the ICU will have MR accompanied by reduced LV systolic function, from either myocardial infarction (MI) or chronic cardiomyopathy. The surgical management of patients with MR and advanced systolic heart failure remains controversial.

Etiology

MR may be caused by abnormalities of any component of the mitral apparatus: annulus, valve leaflets, chordae tendineae, papillary muscles, and adjacent LV free wall [93] (Table 192.2). Common causes of acute MR include chordal rupture from mxyomatous degeneration, blunt trauma, or endocarditis; leaflet perforation from endocarditis or leaflet avulsion from trauma; papillary muscle infarction with rupture; displacement of the papillary muscles from adverse LV remodeling due to ischemic or nonischemic cardiomyopathy; acute rheumatic carditis or other acute condition like stress cardiomyopathy; and mitral prosthetic paravalvular leak [94–97]. Often, the causes of MR are divided into primary disorders involving the mitral valve leaflets or chordae, or “functional” disorders in which the leaflets are relatively normal, but the MR is secondary and is caused by tethering of the mitral apparatus from ventricular remodeling; LV and annular dilatation; and increased sphericity. This classification emphasizes on when attention should be directed toward mitral valve surgery and/or to address an underlying cardiomyopathy.

| TABLE 192.2 Causes of Chronic Mitral Regurgitation |
Mitral Annulus Disorders
Infective endocarditis (abscess formation)
Trauma (valvular heart surgery)
Paravalvular leak due to suture interruption (surgical technical problems or infective endocarditis)

Mitral Leaflet Disorders
Infective endocarditis (perforation or interfering with valve closure by vegetation)
Trauma (tear during percutaneous balloon mitral valvuloplasty or penetrating chest injury)
Tumors (atrial myxoma)
Myxomatous degeneration
Systemic lupus erythematosus (Libman–Sacks lesion)

Chordae Tendineae
Idiopathic (spontaneous)
Myxomatous degeneration (mitral valve prolapse, Marfan syndrome, and Ehlers–Danlos syndrome)
Infective endocarditis
Acute rheumatic fever
Trauma (percutaneous balloon valvuloplasty, blunt chest trauma)

Papillary Muscle Disorders
Coronary artery disease (causing dysfunction and rarely rupture)
Acute global left ventricular dysfunction
Infiltrative diseases (amyloidosis, sarcoidosis)
Trauma

Ischemic MR refers to MR that develops in the wake of an MI. The most important mechanism of ischemic MR is mitral valve leaflet tethering due to chronic post-infarction remodeling, resulting in apical and lateral displacement of the papillary muscles [98]. This shape change occurs after an inferior or posterior transmural MI leads to displacement of the posteromedial papillary muscle [99]. After MI, the presence of MR can augment post-infarction remodeling, further exacerbating the degree of functional MR [100]. Papillary rupture is a rare complication of acute MI (1% to 3%) with a bimodal peak at 1 day, then 3 to 5 days post-MI. The posteromedial papillary muscle has a single blood supply from the right coronary or left circumflex artery and, thus, is 6 to 10 times more likely to rupture than the anterolateral papillary, which has a dual blood supply. Dynamic MR can occur during episodes of transient ischemia involving
the papillary muscles, but is not usually severe [101]. Dynamic MR is also a feature of HOCM and has been observed in some patients with stress cardiomyopathy.

**Pathophysiology**

In acute MR, the LV ejects blood into a small, noncompliant LA, leading to a rapid rise in LA pressure during systole. The difference of LA compliance explains why chronic MR (increased compliance) can be well tolerated, and why acute MR (reduced compliance) is not. The rise of LA pressure is transmitted to the pulmonary venous bed and leads to pulmonary edema, which may be asymmetric if there is an eccentric jet of MR directed to a particular pulmonary vein. The severity of pulmonary edema may be relatively less for patients whose LA has been conditioned by some degree of chronic MR. Large V waves are typically inscribed in the LA and PCW tracings during ventricular systole in acute MR [102]. Such V waves may also be seen with other conditions as well, including LV failure and acute ventricular septal rupture. During acute MR, LV systolic function may be normal, hyperdynamic, or low, depending on the etiology of MR. Tachycardia may temporarily preserve forward cardiac output, but hypotension, organ failure, and cardiogenic shock may evolve.

**Clinical Manifestations**

**History**

With acute severe MR, symptoms of left heart failure predominate, including dyspnea, orthopnea, and cough. Patients with post-MI papillary muscle rupture may have concurrent angina, dyspnea, and abrupt hemodynamic compromise. Spontaneous chordal rupture from myxomatous degeneration may be accompanied by chest pain in nearly half of patients. Symptoms like fevers, chills, malaise, and anorexia may be present in patients with endocarditis (Table 192.3).

p. 1851

p. 1852
### Etiology
- Ruptured chordae, endocarditis, trauma
- 1 or 3–5 d post-MI
- Ischemic heart disease, dilated cardiomyopathy

### Presentation
- Acute pulmonary edema
- Sudden onset pulmonary edema and cardiogenic shock
- CHF and pulmonary edema

### Clinical Examination
- **Point of maximum impulse/apex beat**
  - Normal or displaced thrill
  - Usually normal if no prior LV dysfunction
  - Displaced
- **Murmur**
  - Holosystolic, Loud
  - May be very soft or absent
  - Early systolic, rarely holosystolic Soft
- **Sounds**
  - Third heart sound, second heart sound split
  - Decreased sounds
  - Third heart sound

### Investigations
- **Electrocardiogram**
  - Normal
  - Acute MI
  - Left bundle branch block
- **Chest radiograph**
  - Normal heart size
  - Usually normal
  - Cardiomegaly
- **Echocardiogram**
  - Two-dimensional
    - LV and LA size normal
    - Normal LV
    - LV and LA dilated
    - Annular dilatation
    - Tenting of mitral valve leaflets
    - Restrictive filling
  - Ruptured chord
    - Ruptured head of papillary muscle
  - Doppler
    - Pulmonary venous flow reversal
    - Unimpressive color
    - Restrictive filling
  - Quantitation
    - Large regurgitation volume
    - Free-flow MR
    - Variable regurgitation volume
    - Dynamic effective
Physical Examination

Patients with acute severe MR are tachycardic and tachypnic. Blood pressure is variable, though pulse pressure is often narrow owing to reduced forward stroke volume. Jugular venous pressure may be normal or elevated. Rales or wheezes may be audible over the lung fields, and may be asymmetric. The precordium is often hyperdynamic with a palpable apical thrill. S1 is normal or decreased in intensity, whereas S2 may be widely split because of early closure of the aortic valve. A diastolic filling complex may be appreciated and consists of a third heart sound (S3), and a short mid-diastolic rumble from increased transmitral diastolic flow. The systolic murmur of acute MR may be highly variable, and even absent in up to half of cases of post-MI papillary muscle rupture. The murmur of acute MR is usually not holosystolic, but rather early to mid-systolic in timing, with a crescendo–decrescendo configuration, and is coarse rather than high pitched. These features reflect the rapid LA pressure rise and diminution of the LV–LA pressure gradient throughout systole. The murmur of chronic MR, in contrast, is holosystolic (plateau) owing to the persistent LV–LA gradient during systole. The murmur of acute MR is usually loudest at the left sternal border or apex and the location of radiation may provide a clue as to etiology. Anterior leaflet prolapse or flail produces a posteriorly directed jet, so the murmur typically radiates to the axilla and back. With posterior leaflet involvement, the jet is directed anteriorly and is transmitted to the base, where it may be confused with AS.

Investigations

Electrocardiogram

ECG may show sinus tachycardia or an atrial arrhythmia, such as AF. LA abnormality may be discernible if P waves are present, though signs of LV chamber enlargement are rare in the acute phase. With post-MI papillary
muscle rupture evidence of an evolving inferior-posterior or lateral MI may be seen.

Chest Radiograph

In acute MR, the cardiac silhouette is normal in size despite the present of alveolar pulmonary edema. Asymmetric edema may be present in patients with a flail leaflet producing an eccentric MR jet, particularly in the right upper lobe [103]. Decompensated chronic MR may have associated cardiomegaly, LA enlargement, and prominent pulmonary arteries.

Echocardiography

Prompt TTE is the most important study for patients with suspected acute MR (Fig. 192.12). TTE can delineate mitral anatomy, characterize severity, and document underlying LV function and coexisting valvular pathology. Flail leaflet may be diagnosed by rapid movement of a portion of leaflet/chordal tissue posteriorly into the LA during systole. Chordal rupture, leaflet vegetations, and periannular abscess may be identified in endocarditis. Among patients with functional MR, LV remodeling may be evident along with annular dilatation, papillary muscle displacement and leaflet tethering. Semiquantitative assessment of MR severity can be performed with color flow and continuous wave Doppler interrogation. MR severity correlates with vena contracta width; LA jet width area; pulmonary vein systolic flow reversal; effective regurgitant orifice area; and regurgitant fraction and volume [104,105]. An integrated approach is necessary (Table 192.4). TEE can further characterize mitral valve anatomy and MR severity if TTE images are suboptimal or when complicated IE is suspected. TEE is routinely performed at the time of MV surgery.
**FIGURE 192.12** Mitral regurgitation. A: Color-flow Doppler image from the apical four chamber view of a patient with myxomatous degeneration of the mitral valve with posterior leaflet prolapse producing an anteromedially directed jet of severe mitral regurgitation against the inter-atrial septum. Eccentric jets are common in prolapse and/or flail leaflet and are directed opposite the involved leaflet. B: The “V” wave of mitral regurgitation. This hemodynamic tracing shows a large LA “V” wave (arrowheads) occurring during ventricular systole in a patient with atrial fibrillation (“A” wave absent). Following the “V” wave there is a rapid fall in LA pressure, along the course of the declining LV pressure. In diastole, LA and LV pressures are equalized. The arrow indicated the “C” wave deflection. Giant “V” waves are defined by an increase in >10 mm Hg from mean pressure and are consistent with mitral regurgitation, but may be blunted in patients with large and compliant left atria.

**Cardiac Catheterization**

Catheterization is rarely required to define MR etiology or severity. If there is a discrepancy between clinical findings and noninvasive imaging or when estimated pulmonary artery pressures are out of proportion to the degree of MR, then invasive hemodynamic assessment is indicated. MR severity may be qualitatively assessed by contrast ventriculography. Coronary angiography typically precedes surgery for patients with coronary risk factors and in those with suspected post-MI papillary rupture or dynamic, ischemic MR. Right heart catheterization with oximetry can be done to distinguish acute post-infarction MR from VSD when the TTE is not diagnostic.

**Intensive Care Unit Management**

**Medical Therapy**
The goal of medical therapy for acute severe MR is to stabilize the patient in anticipation of surgery. Afterload reduction with intravenous vasodilators is the mainstay of therapy. Sodium nitroprusside is preferred, though its extended use requires monitoring of thiocyanate levels [67]. Inotropes such as dobutamine or dopamine may occasionally be required to support cardiac output and arterial pressure. IABP for mechanical afterload reduction may be particularly helpful for reducing regurgitant volume and decreasing LV end-diastolic pressure. If end-organ hypoperfusion or hypotension indicates that cardiogenic shock is present, IABP should be promptly initiated as a bridge to surgery. Loop diuretics may help ameliorate pulmonary edema.

Adjunctive medical therapy is driven in part by suspected etiology. For example, antibiotics are indicated for IE and anti-ischemic therapy is required for post-MI papillary muscle rupture [106]. With medical therapy alone, the mortality after papillary rupture is 80% [107]. Although percutaneous coronary intervention (PCI) may help relieve MR in the setting of acute MI, severe MR even without papillary muscle rupture will most often require surgical correction, despite successful coronary reperfusion. Despite recent advances of percutaneous valve repair techniques, none has yet been tested in the setting of acute MR [108,109]. Percutaneous mitral leaflet edge-to-edge repair has been approved in the USA for the treatment of patients with chronic, primary MR, severe heart failure and high surgical risk. It is not yet approved in the USA for the treatment of functional MR. There are numerous transcatheter devices under investigation for use in the treatment of chronic, functional MR. Cardiac resynchronization therapy, when indicated by heart failure symptoms and a wide left bundle branch QRS complex, may help reduce chronic, functional MR related to contractile dyssynchrony, but has no role in the acute setting [110].

**Surgical Therapy**

Surgery is indicated for the treatment of acute severe MR [30]. In contrast to acute severe AR, many patients with acute severe MR may be stabilized over the course of a few days with IABP or inodilators to allow operation under less urgent circumstances. Also, unlike acute AR, acute severe MR may be treated with either repair or replacement, depending on the anatomic findings. Valve repair is the preferred surgical therapy when possible for patients with primary MR. Replacement is necessary, however, with papillary muscle rupture [111]. Mitral repair involves valve reconstruction using a variety of valvuloplasty techniques and insertion of an annuloplasty ring. In addition to reducing the need for anticoagulation and the risk of late prosthetic valve failure, valve repair preserves the integrity of the subvalvular apparatus, which maintains LV
function to a greater degree. Valve replacement with chordal sparing is needed when there is destruction, distortion or infection of the native tissue that makes repair impossible. The decision between repair and replacement for severe ischemic MR can be challenging and is usually left to the discretion of the surgeon [112,113]. There is a high rate of recurrent MR after annuloplasty repair of ischemic MR [40]. Surgical strategy can be guided by intraoperative TEE and direct visual inspection after the patient is placed on cardiopulmonary bypass.

Surgical outcomes depend on age; underlying LV function; presence of concomitant coronary disease; patient comorbidities; and the etiology of MR [114]. IE has a high mortality rate even with medical and surgical therapy, though mortality has decreased with improvements of operative technique and more widespread use of mitral repair [115,116].

The surgical approaches for patients with MR accompanied by advanced systolic heart failure continue to evolve and remain controversial [117]. There is a broad consensus that patients with chronic functional MR and heart failure should be optimized with medical therapy; evaluated for revascularization when coronary disease is present; and considered for cardiac resynchronization therapy (CRT) when indicated [118]. After these steps, reconfirmation of MR severity is required before considering MV surgery. When severe MR is present, a careful integrated assessment of viability, mitral anatomy, and patient comorbidities must be made in consultation with the heart valve team [117]. As percutaneous and alternative approaches to mitral valve disease for patients with heart failure continue to evolve, ongoing clinical trials will help refine the selection of candidates for mitral surgery and determine outcomes of mitral repair versus replacement.
TRICUSPID REGURGITATION

Most ICU patients with TR have functional TR rather than a primary valvular abnormality. Functional TR is produced when the tricuspid annulus is dilated owing to RV enlargement for any reason, including left heart disease or pulmonary hypertension. The most important cause of primary TR encountered in the ICU is IE, particularly among injection drug users [52]. TR can also be produced by leaflet trauma from pacemaker or defibrillator leads or after endomyocardial biopsy. When severe, TR may contribute to symptoms of right heart failure, including fatigue, edema, and ascites. The murmur of TR usually increases in intensity with inspiration (Carvallo’s sign). Examination of the neck veins reveals CV waves. A pulsatile liver edge may also be felt in the right upper quadrant.

Treatment of TR depends on its cause and severity. The vast majority of patients with acute TR due to IE are managed medically. TV surgery during the acute phase of the disease and prior to completion of a course of antibiotics is rarely indicated. Surgery for other causes of primary TR, such as carcinoid, is not a scenario that is encountered in an ICU setting. TV surgery at the time of left-sided surgery (usually MV surgery) is routinely performed when TR is severe or when TR is only mild–moderate, but the TV annulus is dilated beyond 40 mm. Late reoperation for isolated severe TR many years after MV surgery is associated with high morbidity and mortality [40].
The choice of valve prosthesis (Fig. 192.13) is informed by consideration of patient age; the need for anticoagulation; hemodynamic profile; expected durability; and patient preferences and values [119]. Mechanical valves have excellent durability and hemodynamic performance, but require life-long anticoagulation to prevent thromboembolic complications [120]. In contrast, the principal advantage of bioprosthetic valves is the reduced risk of thromboembolic complications after 3 months, except when there are other risk factors such as a hypercoagulable state or chronic AF [121]. Bioprosthetic valves are usually xenografts (porcine or cryopreserved, mounted bovine pericardium); homografts from human cadavers are often used to treat aortic valve and root endocarditis [122]. The Ross procedure for treatment of bicuspid aortic valve disease involves using the patient’s native pulmonary valve to replace the aortic valve (pulmonary autograft) and a homograft to replace the native RV outflow tract. Bioprostheses may develop structural valve deterioration (SVD), which is mostly a function of patient age at implant. SVD occurs more rapidly among patients less than 40 years of age, compared with patients over 65 years of age. Rates of SVD may not differ between homograft and xenograft valves. Over the past 10 years, there has been a clear and significant trend toward the use of bioprosthetic valves in relatively younger patients (ages 50–65), despite the inherent risk of SVD and need for reoperation, given the increased durability of the current generation xenograft valves; decreased risk at reoperation; availability of transcatheter valve-in-valve implantation; aggregate risks of long-term anticoagulation; and patient values and preferences [50,123].
All prosthetic valves are subject to dysfunction that can lead to significant hemodynamic compromise. Common prosthetic valve abnormalities include mechanical valve thrombosis; prosthetic valve endocarditis; structural deterioration and failure; and paravalvular regurgitation with or without hemolysis.

**Prosthetic Valve Thrombosis**

Prosthetic valve thrombosis (PVT) is any valve thrombus attached to or near an operated valve that occludes part of the blood flow path or interferes with the function of the valve [30]. PVT is a rare but life-threatening condition (Fig. 192.14). It is more common with older generation mechanical valves, particularly in the setting of inadequate anticoagulation. The incidence is estimated to be between 0.3% and 1.3% per year in patients with mechanical valves [122, 124, 125].
Clinical Presentation and Investigations

PVT follows a rapid clinical course, unlike the in-growth of pannus tissue within a prosthetic valve ring, which slowly gives rise to valve dysfunction and stenosis [126]. PVT manifests as abrupt onset of systemic embolization; congestive heart failure; or cardiogenic shock. The degree of hemodynamic compromise is determined by valve position and degree of resulting dysfunction. The physical examination may be unrevealing, though soft mechanical valve closure sounds or a pathologic murmur may be present. Mitral PVT is more common than aortic PVT.

A subtherapeutic international normalized ratio (INR) of a patient with a mechanical valve is a red flag for PVT [127]. Rapid diagnosis depends on prompt TTE or fluoroscopy, though both modalities may be complementary [128]. TTE can diagnose the presence of valve thrombus, its composition, and associated functional stenosis or regurgitation. TEE usually provides further risk stratification, particularly for cases of suspected mitral PVT and when TTE windows are inadequate [129].
Fluoroscopy can be useful to characterize tilting-disc or bileaflet mobility. Excursion of tilting-disc mechanical valves is much better appreciated with fluoroscopy than with TTE. There is increasing use of cardiac CT for characterization of prosthetic valve function when thrombosis is suspected [130]. A multimodality imaging approach is usually employed in rapid succession, beginning with TTE, followed by TEE, and then the other modalities as needed. Measurement of thrombus burden by TEE may be important for therapeutic decision-making.

**Intensive Care Unit Management**

Initial management should focus on systemic anticoagulation with intravenous heparin to prevent thrombus extension. Small thrombi without hemodynamic compromise are often treated with anticoagulation alone, whereas larger thrombi require either systemic fibrinolytic therapy or surgery [131,132]. Fibrinolytic therapy is associated with risks of life-threatening hemorrhage and systemic embolization and thus is often delivered in the ICU for purposes of monitoring. The risk is low with right-sided PVT and higher with left-sided PVT, with a risk of cerebral embolism of 12% to 15% [133–135]. Fibrinolysis is considered the first-line therapy for patients with right-sided PVT, and for those with left-sided PVT, small thrombus burden, and NYHA Class I–II symptoms [30]. Fibrinolysis is less useful and potentially more harmful if LA thrombus is present, if the valve thrombus is >2 weeks old, or if PVT is accompanied by shock. TTE after fibrinolysis can monitor for thrombus resolution and dictate additional fibrinolysis for residual thrombus [136]. Alteplase is the most commonly used fibrinolytic for PVT, though urokinase and streptokinase have been used. The typical dose is 10 mg bolus followed by an infusion of 90 mg over 2 hours. An alternative protocol utilizing a slow infusion of low-dose alteplase (e.g., 25 mg over 5 hours without a bolus) has been shown to be effective and safer for pregnant women with mitral PVT [137]. After successful fibrinolysis, unfractionated heparin should be initiated along with warfarin until an INR of 3.0 to 4.0 is achieved for patients with a prosthetic aortic valve or INR 3.5 to 4.5 for a prosthesis in the mitral position [30].

Emergency operation is recommended for patients with hemodynamic instability, NYHA Class 3 to 4 symptoms, or a large clot burden (> 0.8 cm²) [30,43]. Perioperative mortality rates approach 15% and are highest for PVT in the mitral position. A bioprosthesis is recommended after surgery for PVT to reduce future risk of valve thrombosis.

**Prosthetic Valve Endocarditis**

The incidence of prosthetic valve endocarditis (PVE) is 0.5% per year
even with appropriate antibiotic prophylaxis and accounts for 7% to 25% of all cases of endocarditis in the developed world [53]. Endocarditis of a prosthetic valve is a devastating disease that carries a mortality rate of 30% to 50% over 6 months. This high mortality reflects not only a more serious infection but also the difficulty in eradicating the infection with antibiotics alone [138,139]. Infection may involve any part of the valve prosthesis, but the sewing ring may be particularly vulnerable. Sewing ring infection may result in abscess formation, paravalvular regurgitation, and further penetration into adjacent cardiac structures. The risk of PVE may be higher with mechanical valves during the first few months after implantation, but long-term risk is comparable for mechanical and bioprosthetic valves [52]. Infection with coagulase-negative staphylococci is common within the first postoperative year; S. aureus and streptococci species dominate in later years [140–142].

Fever is the most common symptom and may be associated with other signs of prosthetic valve dysfunction including congestive heart failure, a new murmur, or embolic phenomena. Blood cultures should be drawn prior to antibiotic therapy in any patient with a fever and a prosthetic valve. TEE is essential because of its greater sensitivity and specificity in detecting signs of PVE including vegetations, paraprosthetic abscess, or new paravalvular regurgitation [143,144]. There is increasing experience with PET-CT to visualize the extent of infection and screen for extracardiac foci of infection when clinically appropriate.

Eradication of the infecting pathogen with antimicrobial therapy alone is often impossible and depends on the virulence of the organism and extent of infection. Medical therapy is more likely to be successful for late PVE or with non-staphylococcal bacterial infections [145]. Surgical consultation should be sought early in the course of PVE. Indications for surgical therapy include failure of medical treatment marked by persistent bacteremia; hemodynamically significant prosthesis regurgitation with LV dysfunction; large vegetations; paravalvular extension with abscess or conduction defects; or development of intracardiac fistulas [30]. Surgery is almost always required for cases of S. aureus PVE. Infection with S. aureus is a marker for hospital mortality.

**Structural Valve Deterioration**

Failure of mechanical valves in the absence of infection is rare. Mechanical failure from strut fracture often presents with dyspnea; acute heart failure; and hemodynamic collapse with a physical examination marked by absent valve clicks. Death from mechanical valve strut fracture ensues rapidly if the valve is in the aortic position; patients with mitral valve failure can often be stabilized prior to surgery.
With conventional stented bioprostheses, freedom from SVD is 70% to 90% at 10 years, and 50% to 80% at 15 years [139,146]. SVD of bioprostheses is often related to tearing or rupture of one prosthetic valve cusp or progressive calcification and immobility [147]. Risk factors for SVD include younger age at implant; mitral valve position; renal insufficiency; and hyperparathyroidism [148]. Evaluation for SVD requires TTE and often TEE with care to exclude endocarditis as a complicating feature. SVD is the most common cause of reoperative valve replacement in patients with a bioprosthesis. Indications for reoperation are similar for those with native valve disease and are dominated by the development of heart failure. Transcatheter valve-in-valve implantation offers an alternative to reoperation for selected patients [50].

Paravalvular Regurgitation

Paravalvular regurgitation is most often caused by infection; suture dehiscence; or fibrosis and calcification of the native annulus, leading to inadequate contact between the sewing ring and annulus. Mild paravalvular regurgitation on perioperative echocardiography has a benign course with reoperation required in <1% of patients at 2 years [149]. For patients with more severe paravalvular leak, a close follow-up is required, and surgical intervention is warranted for those who develop symptoms, progressive LV dysfunction, or hemolysis. A large proportion (>50%). of mechanical valve patients have some degree of mild intravascular hemolysis marked by anemia and an elevated lactate dehydrogenase (LDH). Paravalvular leaks, particularly small leaks, can lead to more severe anemia caused by shearing of red blood cells. Severe, refractory anemia that is not responsive to iron, folate, and erythropoietin is an indication for repeat valve operation or closure of the paravalvular leak with transcatheter techniques [150]. For high-risk patients not suitable for reoperation, transcatheter closure of the paravalvular leak may be achieved in selected cases with the use of a septal or ductal occluder device [151,152].
PREVENTING INFECTIVE ENDOCARDITIS

Emerging data on the lifetime risk of IE, as well as trends of antibiotic resistance and antibiotic-associated adverse events, have led to changes in guideline recommendations for antibiotic prophylaxis [54]. Infective endocarditis is much more likely to occur from frequent exposure to random bacteremia associated with daily activities than from medical or dental procedures. Antibiotic prophylaxis for IE should only be provided to patients at greatest risk for complications from endocarditis, including patients with prosthetic valves, previous endocarditis, complex congenital heart disease, or cardiac transplantation. Routine antibiotic prophylaxis for mitral valve prolapse is no longer recommended [30,145]. Advances for valvular heart disease are summarized in Table 192.5.

TABLE 192.5 Advances in Valvular Heart Disease

- TAVR for calcific AS is now considered for prohibitive-, high-, and intermediate-risk patients as assessed by the STS Risk Score in conjunction with frailty assessment and patient preference. Challenging decision-making around transcatheter valve therapies has led to establishment of multidisciplinary heart valve teams that include interventional cardiologists, cardiac surgeons, imaging specialists, anesthesiologists, and intensivists.

- Bioprostheses are now in more widespread use than mechanical valves to treat aortic stenosis owing to improved bioprosthetic durability and the absence of obligate anticoagulation. Bioprosthesis are nevertheless prone to degeneration and restenosis. Valve-in-valve TAVR can now be considered for use to treat aortic stenosis due to prosthetic valve degeneration [50]

- Low-flow, low-gradient aortic stenosis, though traditionally recognized in patients with reduced EF, has also been appreciated in patients with normal EF (≥50%) [153]. Referred to as “paradoxical” low-flow, low-
gradient AS, patients often have concentric LV hypertrophy and carry worse prognosis than patients with high-gradient severe AS.

- For patients with a congenital bicuspid aortic valve, the aortic root or ascending aorta should be repaired or replaced in asymptomatic patients if the diameter of the aortic root or ascending aorta is ≥5.5 cm. However, if the patient has an additional risk factor such as a family history of aortic dissection or an aortic growth rate ≥0.5 cm/y, surgery should be considered when the aorta measures ≥5 cm. Aortic surgery in patients with bicuspid valve should also be performed in patients undergoing aortic valve replacement for stenosis of regurgitation if the aortic root or ascending aorta is ≥4.5 cm [154]

- Mitral regurgitation has been reclassified according to primary and secondary etiologies. Primary MR results from mitral leaflet prolapse, restricted leaflet motion from rheumatic or radiation heart disease, or infective endocarditis. Secondary causes include coronary artery disease and cardiomyopathy resulting in displacement of the mitral apparatus. There is a Class I recommendation for surgery only for primary MR when both symptoms and LVEF >30% are present, or in asymptomatic patients with severe primary MR who demonstrate progressive LV remodeling manifested as LVEF 30%–60% or LV end-systolic dimension ≥40 mm [30]

- Endovascular edge-to-edge mitral valve clipping can reduce mitral regurgitation and stimulate reverse remodeling, offering an alternative to surgical repair for primary degenerative mitral valve regurgitation [155]. Clinical trials are ongoing for the use of percutaneous edge-to-edge repair in high surgical risk patients with symptomatic severe functional (secondary) mitral regurgitation.

- Direct oral anticoagulants are not recommended for use in patients with mechanical heart valves owing to concerns about increased risk of thromboembolic and bleeding events [156]

TAVR, transcatheter aortic valve replacement; AS, aortic stenosis; STS, Society for Thoracic Surgeons; EF, ejection fraction; LV, left ventricular;
MR, mitral regurgitation; LVEF, left ventricular ejection fraction.

INTRODUCTION

Acute aortic syndromes represent a spectrum of entities characterized by disruption of the integrity of the aorta wall threatening central pressure, vital organ perfusion and survival. They include acute aortic dissection, intramural hematoma (IMH), penetrating aortic ulcer (PAU), expanding aortic aneurysm, and aortic trauma [1,2]. Although the classical presentation of “aortic agony” is characterized by severe, sudden-onset pain in the chest or back, this presentation, although recognizable, occurs only among a minority of cases [3]. As the initial manifestations of acute aortic syndromes are highly variable and establishing the diagnosis requires specific testing, arriving at the appropriate diagnosis in a timely manner is often challenging. Owing to the early mortality risk [4], prompt recognition of the acute aortic syndromes enables early treatment decision-making potentially improving outcomes. Frequently, the clinician must depend on subtle findings gleaned from history, detailed physical examination, and imaging in order to decide on an appropriate treatment plan [5]. This chapter reviews the spectrum of acute aortic syndromes, including acute aortic dissection, acute aortic IMH, PAU, and rupture of aortic aneurysm. Because patients with suspected acute aortic syndromes are frequently critically ill and require rapid disposition to treatment, evaluation, and treatment algorithms are described, with each individual section serves as a guide to a syndrome-specific evaluation. Key features of a focused history and physical examination are emphasized. In addition, critical laboratory and imaging tests are reviewed.

AORTIC DISSECTION

Definition and Classification

Dissection of the aortic wall involves longitudinal cleavage of the muscular media, leading to the formation of a second (or false) vessel lumen. The inciting event for a typical aortic dissection is thought to be a tear in the intima that leads to exposure of the underlying media, generally weakened by medial degeneration. Once created, this cleavage front advances due to wall strain that can be created at physiologic levels of blood pressure. The cleavage front typically advances in the direction of blood flow, but dissection against the direction of flow is also observed.

There are multiple consequences of dissection. The false lumen may have little or now outflow leading to increased pressure relative to the native (or true) lumen, leading to compression and potentially compromised downstream blood flow. The resulting intimal flap may also involve or obstruct branch vessels leading to end-organ malperfusion that can result in stroke, limb ischemia, or visceral malperfusion. Owing to the resulting weakening of the aortic wall, the damaged aorta may therefore be more prone to rupture.

Aortic dissections are generally classified by location and extent. There are two commonly used classification systems (Fig. 193.1). The DeBakey system includes three types of aortic dissection [6]. Type I involves dissection of both the ascending and descending aorta, and/or the arch. Type II dissection involves only the ascending aorta proximal to the brachiocephalic artery, and type III involves only the descending aorta distal to the left subclavian artery [6]. The Stanford system includes two dissection types. All dissections involving the ascending aorta are included in Type A: this includes Types I and II in the DeBakey system. Stanford Type B includes all dissections that do not involve the ascending aorta [7]. Classification of the location of a dissection carries prognostic and treatment importance. Surgery is indicated for dissection of the ascending aorta, whereas medical management is frequently the treatment of choice for descending dissection without associated end-organ malperfusion or impending rupture. The optimal treatment for isolated arch dissection (also called non-A and non-B dissection) is debated [8].
Chronicity of the dissection is defined as the time interval between onset of symptoms and evaluation. Dissections that are present for less than 2 weeks are defined as acute, whereas those that are present longer are defined as chronic [1]. This has been further divided into hyperacute (<24 hours), acute (2 to 7 days), subacute (8 to 30 days), and chronic (>30 days) with these time categories associated with survival [9]. It is noteworthy that the mortality associated with untreated ascending aortic dissection reaches up to 75% at 2 weeks [10].
CLASSIC AORTIC DISSECTION

Epidemiology

Estimates of the incidence of aortic dissection range from 3 to 16 cases per 100,000 per year [1,4,11]. The highest incidence occurs in the sixth and seventh decades of life among patients with hypertension [1,4,11]. Although a male predominance is traditionally described, at age 75 or above the incidence is similar in men and women [4,5]. Younger patients without a history of hypertension may present with acute aortic syndromes generally in the setting of a family history, connective tissue disease, vascular inflammatory disease, or trauma; therefore, this diagnosis should not be discounted for the young. Age may also influence presentation with complicated Type B dissection [12]. The aorta may be disrupted in the setting of trauma or during procedures (iatrogenic) with the latter described occurring at approximately 0.15% [13]. A proportion of patients suffering iatrogenic dissection may in fact have medial degeneration and therefore an underlying susceptibility [13]. Acute aortic syndromes have been described in the setting of cocaine use, possibly related to abrupt changes in heart rate in blood pressure, and are most often Type B in young, urban, male smokers.

Mortality rates associated with dissection are very high, and many patients do not survive to hospital admission. Overall 30-day mortality for aortic dissection of any type is greater than 50% [3,4]. In one community-based cohort study, nearly 50% of patients with dissection died before hospitalization. Thirty-day survival for those admitted alive was only ∼50% [3,4].

Outcomes of patients presenting with acute aortic syndromes vary by type and the presence of anatomic complications. Recent studies describe the mortality for medically managed Type A dissection at 0.77% per hour with historical data sets quoting even higher rates [3,14]. Early mortality may be due to complications including cardiac tamponade, aortic regurgitation, stroke, or compromised myocardial perfusion [15,16]. For iatrogenic dissection, mortality may be as high as 30% to 40% [17].

Overall, Type B dissection is associated with a lower mortality than Type A with early rates of 13% and 5-year rates of 33% [4,18]. In reality, however, the morbidity and mortality of Type B dissection are variable and depend on the anatomic extent as well as the presence of complications. It is estimated that as many as one in five patients with Type B dissection develop malperfusion and approximately 25% require an intervention during the index hospitalization [1,2,19]. When also including other complications such as periaortic hematoma, refractory
pain, or refractory hypertension, the proportion of patients with complications during the index hospitalization for Type B dissection approaches 50% [18]. For patients who present with or develop complications, in-hospital mortality is ∼20% while it is 6% for uncomplicated Type B dissection [18]. Age has been shown to have an important impact for patients with complicated Type B dissection with mortality among patients less than 70 years old of 10% versus 30% among patients older than 70 with a ∼2.4-fold risk of mortality after adjustment for baseline differences [20]. For patients who present without complications and are medically managed, there is long-term risk of complication including aneurysm and expansion necessitating close follow-up [21].

**Etiology and Pathophysiology**

Any process that causes damage to the aortic tunica media, leading to medial degeneration, increases the risk for aneurysm or dissection. Although this medial disruption is a defining feature of acute aortic syndromes, cases of isolated intimal tears without hematoma formation have been described [1]. In the case of typical aortic dissection, the precipitating event is thought to be the creation of a tear in the intimal layer overlying a damaged area of the media. In the elderly patient with dissection, the presence of medial degeneration is correlated with the effects of aging, hypertension, and atherosclerotic disease [1]. Indeed, hypertension is found among 70% to 80% of patients with aortic dissection [1,4]. A number of underlying biological processes have been considered as contributing to the etiology of dissection including inflammation, endothelial reactive oxidative stress, and disturbed P53-MDM2 signaling [22,23].

For the younger patient with aortic dissection, medial degeneration is still the culprit, but the constellation of correlated risk factors tends to differ [1,4]. Typically, young patients are more likely to have hereditary connective tissue disorders that compromise the integrity of the extracellular matrix in the tunica media, most notably Marfan syndrome, Loeys–Dietz syndrome, Ehlers–Danlos syndrome, bicuspid aortic valve, or familial thoracic aortic aneurysm syndrome (FTAAS) [24–27]. Among patients presenting with recurrent aortic dissection, approximately 5% of all dissections, Marfan syndrome is often present [28]. Patients, 40 years of age or younger, are also less likely to be hypertensive, and may have a larger aortic diameter on presentation. Paradoxically, mortality of this younger cohort does not appear to be lower than that of older patients. All of these syndromes have been associated with breakdown of the fibrillin and collagen components of the extracellular matrix in the media, leading to medial degeneration. Aortic dissection risk is also
increased in patients with Turner and Noonan syndromes [25]. Increased risk for dissection is found in a number of other conditions, including aortitis, especially in the context of giant cell arteritis and Takayasu arteritis [1,2,29]. Cocaine use has also been associated with dissection, ostensibly on the basis of increases in cardiac output, blood pressure, or as a consequence of direct vascular injury from cocaine itself (i.e., cocaine-induced vasculitis/endarteritis). In particular, crack cocaine has been identified as a potential precipitant of dissection.

Notably, pregnancy is an independent risk factor for aortic dissection [30]. The highest incidence of dissection is observed during the third trimester or early postpartum period [30]. This risk is high particularly among pregnant women with a bicuspid aortic valve, Marfan, Ehlers–Danlos, or Turner syndrome [25,30,31]. Among pregnant women with Turner syndrome, the risk of dissection or rupture exceeds 2%, and the risk of death is increased 100-fold [25,30]. Sporadic aortic dissections may occur among women without these predisposing conditions, possibly due to the elevated expression of relaxin and inhibin associated with pregnancy.

Iatrogenic injury to the aortic wall, sustained in the context of cardiac catheterization, intra-aortic balloon pump placement, or cardiac surgery, increases the risk of future aortic dissection [13,32,33]. Cardiac surgery involving the aortic valve appears to pose the greatest risk [17]. Iatrogenic dissection of the ascending aorta at the time of cardiac surgery is also associated with increased mortality risk with the highest rates for those that occur during the early (42%) or late (32%) postoperative periods compared to those that are discovered intraoperatively (17% mortality) and presumably addressed as part of the index procedure [13,17,34,35]. Aortic dissection after prior aortic valve replacement for bicuspid aortic valve has also been described [36].

Damage sustained by the aorta may take up to several years to develop into aneurysm and/or dissection. Blunt trauma or rapid deceleration injury is frequently associated with injury to the aortic isthmus.

**Clinical Manifestations**

There is no single physical examination finding or lab test that allows for positive identification of dissection: only imaging of the aorta verifies the diagnosis with a high degree of sensitivity and specificity. Consequently, the initial evaluation and examination must incorporate a high index of suspicion and careful assessment.
The classic initial symptom of acute aortic dissection is classically described as the abrupt onset of severe chest or back pain. The severity of this pain is characteristically at its maximum at the point of inception. This is in sharp contrast with the typical crescendo onset of myocardial infarction pain [1,4]. The quality of the pain is often described as being “tearing” or “stabbing” and the pain may radiate or be migratory [1,37]. Although severe pain is described by the majority of patients presenting with acute aortic syndromes, symptoms can be variable depending on the location and extent of the disruption as well as patient factors including gender. A minority of patients present with syncope which is associated with poor outcomes as it may occur in the setting of complications such as stroke or tamponade [38,39]. Focal neurologic symptoms may also be the primary manifestation and may be transient in nature potentially complicating diagnosis [14,37]. The initial location of the pain is correlated to the location of the dissection: of the patients from reported clinical series who presented with anterior chest or neck pain, 65% to 90% were found to have dissection of the ascending aorta. Interscapular or back may also represent dissection of the descending aorta [1]. This variability of presenting symptom presents a challenge for clinicians and may delay diagnosis particularly for those with atypical symptoms [37].

The physical examination of patients with acute aortic syndromes may also be variable. The most common finding at the time of presentation is hypertension; however, the frequency depends on the anatomic classification [1]. Of the patients of the IRAD series, 36% of patients with Type A dissection had elevated blood pressure, whereas 70% of patients with Type B dissection had hypertension. Hypotension may also be a presenting feature of aortic dissection and portends developing shock more frequently for Type A compared to Type B dissections. It is also noteworthy that patients with dissections who present with a “deadly triad” of hypotension/shock, an absence of pain, and evidence of branch vessel involvement exhibit a markedly higher mortality [1,38,40,41]. Pericardial tamponade in the context of Type A aortic dissection is a surgical emergency, as it represents a tenuously compensated rupture of the aorta [39]. Unless the patient is in extremis, pericardiocentesis should not be performed, as the release of pressure from the pericardial space may precipitate a rise in blood pressure, recurrent hemorrhage into the pericardium, and cardiovascular collapse [16,38,39]. Dissection into the pleural space may also lead to hypotension and syncope, and similarly requires immediate surgical intervention. These findings are sometimes attributed to alternative diagnoses such as pleural effusion (either reactive or from hemorrhage) and may occur in as many as 16% of patients [1,3]. On occasion, Type A dissection may extend proximally to the ostia of the coronary arteries, leading to myocardial infarction or involve the aortic valve leading to severe aortic regurgitation [42].
A number of other vascular complications of aortic dissection may be apparent on initial evaluation. A pulse deficit is described in approximately 30% of patients with Type A dissection and is associated with increased mortality [41]. Focal neurologic deficits are described among 17% of patients. These occlusion events are typically the result of the extension of the dissection into a branch vessel (“static” occlusion), occlusion of the ostium of the vessel due to migration of the intimal flap (“dynamic” occlusion), or impaired flow in the true lumen due to distention of the false lumen. The spectrum of clinical findings associated with aortic side-branch involvement ranges from no signs and symptoms, to subtle findings, to florid manifestations, including severe ischemia of the affected territories. The mass effects of the dissection may lead to focal neurologic defects for rare cases. Involvement of a subclavian artery may lead to a difference in measured blood pressure between the two arms or pulse deficit. Impaired flow in the mesenteric arteries leads to signs and symptoms consistent with mesenteric ischemia. Dissections may also lead to occlusion of the renal arteries, leading to acute renal failure, or renal infarction. A pulse deficit is described in approximately 30% of patients with Type A dissection and is associated with increased mortality [41]. Focal neurologic deficits are described in 17% of patients. Rarely, dissection leads to spinal artery occlusion with resultant paraparesis or paraplegia. Lower limb ischemia may also occur in Type B dissection.

**Diagnosis**

A focused history and examination should be performed to assess the pretest likelihood of acute aortic syndrome [1]. Evaluation should include known genetic, connective tissue, or familial conditions associated with aortic disease, history of recent aortic manipulation, typical pain, or high-risk signs such as pulse deficit, blood pressure differential, focal neurologic signs or symptoms, and new murmur of aortic regurgitation [1,29]. Risk scores based on the AHA/ACC consensus guidelines for the diagnosis of acute coronary syndrome have been evaluated and shown to be highly sensitive [43].

The electrocardiogram (ECG) is often (69%) abnormal, but is generally nonspecific [3]. Chest X-ray (CXR) is likewise generally performed and is abnormal for most cases (80%), but findings are rarely specific for acute aortic syndrome [3]. The presence of ST-segment elevation in lead aVR in patients with Type A dissection has been shown to be of prognostic value [44]. Widening of the mediastinum and displacement of aortic calcification are also more common among cases than controls. CXR and ECG may provide value but neither are sensitive for acute aortic syndromes and normal findings should not delay definitive imaging for
patients in whom there is clinical suspicion [1].

There is not yet a specific biomarker in common clinical use that allows the clinician to confirm the diagnosis. D-Dimer, a fibrin degradation product indicative of intravascular coagulation, is widely available and well established for the diagnostic algorithm for pulmonary embolism. A D-dimer >500 ng per mL has been shown to be highly sensitive for acute dissection (~97%, negative predictive value 96%) but relatively nonspecific (56%, positive predictive value 60%) [45–49]. Based on this high sensitivity, D-dimer may be a potential screening tool to “rule out” acute aortic dissection [45]. The kinetics of D-dimer after dissection are not well described posing one possible limitation. One study reported that almost 1 in 5 patients with aortic dissection had D-dimer levels <400 ng per mL illustrating variability of performance [50,51]. In addition, the sensitivity in the setting of isolated IMH or not established. Other biomarkers under investigation include smooth muscle myosin heavy chain protein; however, diagnostic performance still does not exceed that of computed tomographic (CT) or magnetic resonance (MR) angiography [52,53]. Soluble elastin fragment (sELAF) levels have also evaluated, but the performance of assays for this biomarker has not been widely validated [54]. Other available biomarkers such as cardiac troponin and natriuretic peptides are important prognostic markers in most clinical settings but are nonspecific for aortic disruption.

**Imaging**

Prompt imaging is critical during the evaluation of suspected aortic dissection. Multiple modalities are at the disposal of the clinician; however, the patient is best served by the modality that offers high sensitivity and specificity without delay or transport time. The specific technique of choice may differ among hospitals, as not all facilities have the same capabilities. Following is a discussion of the relative strengths and weaknesses of the commonly available imaging techniques used for the diagnosis of aortic dissection. The decision regarding the optimal technique to be used in a specific context is left to the individual clinician. Frequently, multiple imaging modalities must be used for a single patient. In addition, a single patient may require serial studies if his/her signs or symptoms evolve [1].

In most hospital settings, a CXR is performed as a matter of course in the evaluation of chest pain. The CXR may offer much useful information. In the patient with an aortic dissection, the CXR may reveal an abnormal
aortic silhouette, widening of the mediastinum, separation of intimal calcium, pleural effusions, and blunting of the heart boarders representing extravasation of blood into the pericardial space. Although useful, CXR rarely establishes the diagnosis of acute aortic syndrome and is unable to define the total extent or the presence of complications. Therefore, other modalities must be used.

Transthoracic echocardiography (TTE) is a readily available, noninvasive, and portable imaging modality that may be considered. Sensitivity is highest for disruption of the ascending aorta particularly if it involves the root or aortic valve. In addition, complications such as aortic regurgitation and pericardial effusion can be visualized. It should be noted that sensitivity for Type A dissection varies between 70% and 90%, and sensitivity for Type B dissection is approximately 40%. Given this suboptimal sensitivity, performing a TTE should not delay a more sensitive imaging study [1].

In terms of definitive imaging, computed tomographic angiography (CTA), magnetic resonance angiography (MRA) and transesophageal echocardiography (TEE) have enabled diagnosis of acute aortic syndromes with high sensitivity (>95%) and specificity (>95%) (Table 193.1) [1,55–59].

Aortic valve regurgitation
Pericardial effusion
Color Doppler differentiation of flow in dissection-related “true” and “false” lumens

Quickly performed at bedside
No ionizing radiation
Intravenous contrast not required
Image quality not affected by body habitus
Ascending aorta, arch, and proximal descending aorta may be visualized
Aortic valve function can be assessed directly

CT
Intimal flap in aorta
Dilatation of aorta in any segment
Pericardial effusion
Dissection-related “true” and “false” lumens or intramural hematoma accentuated with contrast

Readily available
Noninvasive
Quickly performed
Image quality not affected by body habitus
Full aorta may be assessed in single scan
Most widely used first imaging test in suspected dissection

MRI
Intimal flap in aorta
Dilatation of aorta in any segment
Pericardial effusion
Dissection-related “true” and “false” lumens or intramural hematoma may be differentiated

Noninvasive
No ionizing radiation
Image quality not affected by body habitus
Full aorta may be assessed in single scan
Branch vessel visualization is excellent
Contrast not required to visualize intramural

Not readily available at many hospitals
Transportation to scanner may be required in some centers
Patient monitoring during scan may be difficult
Scan time longer than other modalities
hematoma or to differentiate between true and false lumen
Aortic valve function can be directly assessed

By virtue of the close proximity of the aorta to the ultrasound probe in the esophagus, TEE offers clear views of most portions of the thoracic aorta and affords excellent information regarding aortic valve function. TEE may be useful to guide surgical intervention for Type A aortic dissection. TEE, like TTE, is portable and can be performed easily at the bedside, which makes it the procedure of choice for evaluation of critically ill or physiologically unstable patients who may be at higher risk during transportation for radiographic examinations. In addition, TEE does not require the use of nephrotoxic contrast agents. For aortic dissection, TEE has a sensitivity between 90% and 100%, and specificity is approximately 90%. Color Doppler imaging may identify the blood flow between the true and false lumens. Perhaps the most important procedural drawback regarding TEE is the need for conscious sedation, which may be difficult to administer to a patient who is hemodynamically unstable.

CT scanning allows for a full view of the entire aorta. Consequently, the sensitivity (90% to 100%) and specificity (90%) for visualization of the intimal flap in aortic dissection are comparable to TEE [57]. Specific CT techniques, such as spiral CT, also allow for facile three-dimensional reconstruction. The “double barrel” produced by dissection can be distinct. In classic aortic dissection, an intimal flap can be seen, separating a true and false lumen. Pericardial and pleural effusions are often easily visualized, but blood flow and tamponade physiology cannot be assessed directly. Dedicated aortic CT scans should compensate for
cardiac motion through tools such as ECG gating [57]. In addition, noncontrast images should also be obtained for greater sensitivity for isolated IMH. When obtaining aortic imaging, the full aorta from chest to pelvis should be visualized to determine the full extent of aortic and branch vessel involvement. Imaging only the chest, for example, may result in incomplete characterization and require follow-up testing. The intravenous (IV) contrast required is associated with risks of allergic reactions and contrast nephropathy. Many patients presenting with the acute aortic syndromes may also have renal insufficiency or failure; however, for the critically ill patient in whom aneurysmal rupture is suspected, definitive diagnosis and treatment of the aortic process should take priority.

CT scanning and magnetic resonance imaging (MRI) share several of the same advantages, such as high image resolution and the ability to scan the entire aorta. Overall, the sensitivity and specificity of intimal flap detection by MRI are nearly 100%. MRI does not require the use of IV contrast, which represents an advantage over CT scanning; however, MRI is more expensive and not as readily available or as rapidly performed as CT scanning. The primary limitation of MRI is lack of availability: not all hospitals have MR scanners available for emergent use. Even when available, issues of transporting a potentially unstable patient are still present. MRI is also contraindicated for patients in who have vascular clips, implantable cardioverter-defibrillators (ICDs) or pacemakers.

In the past, retrograde aortography was considered the gold-standard technique for aortic imaging. Because aortography is an invasive test that requires the assembly of a catheterization laboratory team and the use of IV contrast and ionizing radiation, it is typically reserved for those cases where diagnostic uncertainty remains after one or more other imaging studies have been obtained. The ability of aortography to detect aortic dissection depends on the presence of blood flow between the true and false lumens; therefore, for cases where blood flow between these chambers is limited, the aortogram may be nondiagnostic. Overall, among patients with classic aortic dissection, the sensitivity and specificity for intimal flap visualization are 80% to 90% and 90% to 95%, respectively [49]. Aortography is still the study of choice for visualization of aortic branch vessels, which may not be visualized by other imaging modalities as well. In addition, aortography is particularly useful when endovascular treatment is contemplated.

Consultation with an imaging specialist may be useful particularly for determining the optimal diagnostic protocol. At some centers scans protocoted to exclude several acute diagnosis such as pulmonary embolism, dissection, and myocardial infarction, called “Triple Rule-Out” may be obtained; however, they are associated with higher doses of radiation and the clinical utility is debated [55]. In addition, the
sensitivity and specificity of CT or MR may be altered if they are optimized to detect other diagnosis such as pulmonary embolism.

**Management**

The primary goal of treatment for a patient with aortic dissection is to minimize the effects of the dissection while rapidly evaluating the necessity of urgent intervention, if indicated (Fig. 193.5) [60]. Diagnosis, management, and interventional decision-making are complex and time sensitive and acute multidisciplinary response teams may allow for optimized management [61]. Clinical stability should first be assessed to evaluate for acute complications such as tamponade or aortic regurgitation, where traditional pharmacologic interventions may be harmful and urgent surgery is needed. Initial medical management of stable patient while waiting for possible intervention should focus on management of pain, decrease of blood pressure to a minimum acceptable level, and decrease in the force of left ventricular contraction (dP/dt). In general, short acting parenteral therapies are favored in the acute setting to allow titration. Early observation should occur in an intensive care setting, with continuous arterial pressure monitoring. For patients presenting with evidence of heart failure, pulmonary artery catheter placement may be considered, but is usually not necessary.

Pain management is titrated aggressively for patients with dissection. The goals of pain treatment are patient comfort and decrease of adrenergic tone. Narcotic analgesics are effective for the rapid reduction of symptom severity, especially when administered in IV form. Long-acting oral formulations of narcotics are not recommended.

Blood pressure and dP/dt can be decreased with a β-blocker. Noncardioselective agents such as propranolol, labetalol, and esmolol have been used extensively in this context [62]. β-Blockers should be considered even for patients who are not hypertensive at presentation, as the reduction in dP/dt is thought to be beneficial for reducing the advancement of the dissection front. The goal heart rate is 60 beats per minute, and the goal systolic blood pressure is no higher than 120 mm Hg. For patients with hypertension, agents with both α- and β-antagonism such as labetalol may be useful. In the event that a patient’s blood pressure is still elevated even after a goal heart rate has been reached with β-blockade, a vasodilator such as nitroprusside or an IV angiotensin converting enzyme inhibitor, such as enalaprilat may also be administered; however, vasodilator therapy should not be used without concomitant β-blockade, given the possibility of an increase in heart rate and dP/dt accompanying its potent vasodilatory effects [62].

In the rare event that a β-blocker cannot be used, due to contraindications such as bronchospasm, the nondihydropyridine
Calcium-channel blockers are the second-line agents. Verapamil and diltiazem, both of which have vasodilator and negative inotropic/chronotropic effects, may be used.

Close monitoring, including pulse and perfusion monitoring, is required for all patients as complications such as limb or visceral malperfusion may develop after the initial assessment. Hypotension may be seen in conjunction with dissection. It should be noted that the mode of blood pressure measurement should be scrutinized before changing a treatment plan; “pseudohypotension” may occur when dissection propagates into the limb in which blood pressure is being measured. In such cases, it is recommended that hypotension be verified by measurement of blood pressure in other limbs prior to discontinuation of β-blockers or calcium-channel blockers (Table 193.2).

Therapeutic goals include maintenance of systolic blood pressure 100–110 mm Hg, heart rate approximately 60 beats per minute.

**Intervention**

The primary concept that relates to the optimal choice of therapy has not changed for nearly 30 years. In most cases, the location of the dissection determines whether the patient should undergo immediate surgery. Patients who present with acute dissection in the context of pregnancy require additional consideration and multidisciplinary evaluation [63]. Type A dissection is treated with surgery in virtually all cases, as the outcomes associated with surgical repair are superior to outcomes with medical management: ~25% versus ~50% to 70% mortality at 30 days [3,4,64]. In general, preoperative coronary angiography has not been shown to be beneficial and is not recommended [65]. The one potential contraindication to urgent surgical repair of Type A dissection is stroke in evolution depending on severity, due to high risk of hemorrhagic transformation during surgery [15,16]. In aggregate, survival of patients with acute Type A dissection who are treated with surgical repair has improved over the last 25 years [10]. Aortic dissection repair is complex surgery, and each patient’s medical comorbidities need to be addressed in detail before surgery as time allows. In the past, patients older than 80 were thought to have an operative survival rate too low to justify attempted repair. A multicenter study reported acceptable outcomes for aortic dissection repair performed in selected octogenarians. Although this study raises the possibility of aortic dissection repair in this age group, this approach remains controversial and each patient must be approached individually [66]. There is an evolving role of endovascular Type A dissection repair, however, surgical management remains the current standard [67–69].

Patients with Type B dissections are generally managed conservatively. Urgent intervention is warranted in the setting of complications including visceral or limb malperfusion, aortic expansion or impending rupture, progression of dissection, refractory pain, or refractory hypertension [70]. Risk stratification for Type B aortic dissection may be complex and benefit from specialty and multidisciplinary evaluation [71]. Interventional options include open surgery or endovascular techniques including fenestration and stent grafting.

Although there are no randomized assessments in the acute setting, observational studies suggest that outcomes may be better with
endovascular therapy when feasible. Although percutaneous fenestration of the “false” lumen had previously been the therapeutic option of choice in this setting, this technique has been largely supplanted by the more definitive endovascular stent repair. The theory that closure of the primary entry tear may reduce the risk of propagation and further complications, as well as increase the likelihood of false lumen thrombosis, has led to the development and investigation of the use of covered stent grafts for selected patients with aortic dissection. It is thought that the minimally invasive nature of this technique may decrease perioperative mortality and thus improve outcomes [72, 73]. Initial results and short-term outcomes with endovascular therapy of acute Type B dissections are promising [74, 75]. Case series have described this strategy for pregnant women with Type B dissection [76]. Newer technologies using conformable aortic grafts in the aortic arch and thoracic aorta show promising early outcomes [77].

The increasing use of endovascular repair for Type B dissection prompted an expert consensus statement from an interdisciplinary group [72]. Data from 63 studies published between 2006 and 2012, and including 6,729 patients were reviewed [72]. The authors recommended medical treatment for uncomplicated acute Type B dissection but felt that complicated acute Type B dissection should be treated with TEVAR rather than surgery, when feasible and combined with other endovascular interventions such as fenestration, noting a survival benefit with the less invasive approach [72]. Intervention for subacute and chronic Type B dissection was recommended only when complications developed; in these settings as well, TEVAR was favored over surgery when feasible [72]. Nonrandomized observations from IRAD also found that TEVAR was associated with lower 5-year mortality when compared to medical therapy, suggesting that improved techniques may be associated with better outcomes, and prompting a call for further randomized trials [73].

There has been a growing utilization of endovascular stent grafting for uncomplicated Type B dissection in the subacute or chronic phase, particularly when there are markers suggesting an increased risk of adverse remodeling. Prognostic factors described include false lumen size, entry tear size and location, maximum aortic diameter of 40 mm or greater, number of vessels originating from the false lumen, and the patency of the false lumen [78–83]. The INSTEAD trial randomized patients with uncomplicated Type B dissection to medical management or stent grafting [84]. Patients were randomized to treatment between 2 and 52 weeks after dissection (mean time intervals from dissection to randomization 45 days for optimal medical therapy (OMT) vs. 39 days for TEVAR + OMT group). The primary endpoint was all-cause death at 2 years. Secondary endpoints included aortic-related deaths, progression, and aortic remodeling. No differences between groups in either the
primary or secondary endpoint were seen at 2 years [84]. A subsequent exploratory analysis at 5 years suggested remodeling benefit as well as aortic-related mortality and all-cause mortality [85]. A subsequent trial called ADSORB also suggested benefits in terms of aortic modeling parameters [86]. Other nonrandomized assessments of TEVAR for acute uncomplicated Type B dissection in selected patients have also shown lower rates of aortic adverse events and mortality with TEVAR versus medical therapy alone [87]. Although these outcomes have not driven broad utilization of this strategy, there is growing interest in those patients believed to be at risk for complications such as aneurysm formation. Trials exploring composite devices are ongoing [88]. In the chronic phase traditional criteria for intervention are driven by aortic size (≥5.5 cm ascending aorta and ≥5.5 to 6.0 cm descending aorta), its rate of growth over time, and the presence of associated complications such as aortic regurgitation and left ventricular dysfunction of some patients with Type A disease.

Observational series of patients presenting with traumatic aortic disruption have suggested alternative classification systems which may clarify imaging characteristics and their impact on interventional decision-making.

Outpatient Follow-Up and Medical Therapy

Outpatient medications for patients generally should generally be oral long-acting therapies of similar classes to those used in the acute setting [1]. There may be specific benefits to certain classes of agents for patients with connective tissue disease [89]. Patients should be advised to avoid heavy lifting, Valsalva, or other activities that put undue stress on the aorta; however, moderate cardiovascular activity should be encouraged [90–92]. Close follow-up is required for all patients as adverse remodeling may occur in as many as a third of patients, however, achieving high rates of long-term follow-up can be challenging [93].
INTRAMURAL HEMATOMA

Not all cases of apparent aortic dissection involve communication between the true and false lumens via a tear in the intima. In 1988, the first cases of an “atypical” form of dissection without intimal rupture were described [94]. IMH is defined as a spontaneous collection of blood within the aortic media that does not apparently communicate with the lumen. The natural history of IMH is not fully understood. It is thought that it may represent a predecessor of aortic dissection with eventual intimal rupture.

Both classic aortic dissection and IMH are generally associated with the same set of risk factors and may be indistinguishable clinically. Diagnostic imaging studies, notably TEE, CT angiography, or MRI, are required to distinguish them (Fig. 193.2). Characteristic features include a crescentic or circumferential thickening of the aortic wall indicating the presence of fresh thrombus. CT imaging with and without contrast facilitates diagnosis as the hematoma has a higher tissue density than unenhanced blood on noncontrast CT but is without enhancement after contrast administration [1]. Consequences of untreated IMH have traditionally suggest a similar risk for adverse outcomes as with typical aortic dissection; however, more recent data sets suggest variable outcomes.

**FIGURE 193.2** CT angiograms demonstrating the typical appearance of a “classical” aortic dissection versus that of an aortic intramural hematoma. Note the smooth crescentic thickening of the wall of the ascending aorta in the patient with intramural hematoma and the obvious intimal flap seen in the
Epidemiology

IMH occurs among a minority of the patients presenting with an apparent aortic dissection. Acute dissection events included in the IRAD registry were found to be due to IMH 10% of the time. Serial imaging of IRAD patients with IMH revealed that 16% evolved to dissection with intimal tear [5,95]. There was no statistically significant difference of mortality rates for typical dissection and IMH in this series [96]. Other reports suggest that patients with IMH may have better survival and may more often be managed more conservatively than patients with dissection [95,97]. An IRAD report of 178 patients with IMH noted an incidence between 0% and 25% of patients presenting with acute aortic syndromes [94]. The descending thoracic aorta was involved more often (58% Type B, 42% Type A, p < 0.001) [94]. Overall outcomes for Type A and Type B IMH were similar to those for dissection in the same anatomic distributions. IMH was associated with a higher rate of pericardial effusions and periaortic hematomas, but a lower incidence of pulse deficits and aortic regurgitation [94]. In-hospital mortality was high for Type A IMH (26.6%) and higher for those treated medically (40%) compared to those treated surgically (24.1%) although treatment was not randomized [94]. One observational review of 65 patients with IMH found that those with an associated PAU progressed more frequently than IMH without PAU (48% vs. 8% p = 0.002) [98].

Although the risk factors and clinical presentations of classic aortic dissection and IMH are indistinguishable, certain important differences are recognized. Compared to those with typical aortic dissection, patients with IMH tend to be older, tend to have more atherosclerotic disease, and are more likely to have a distal acute aortic syndrome; two-thirds of IMH cases are Type B, in contrast with typical dissections, 65% of which are Type A.

Long-term follow-up of patients with IMH reveals that the hematoma evolves most commonly into a true or false aortic aneurysm or especially when associated with penetrating atherosclerotic ulcer (PAU). Up to 45% of such aneurysms that are located in the ascending aorta lead to rupture. Spontaneous regression occurs in up to one-third of cases. Regression is most likely with IMH not associated with increased aortic diameter at the time of presentation. Some observational data suggest that Type B IMH may have a more benign course than Type B dissection [99]. Clinical and radiographic progression of IMH is more likely when PAU is present (Fig.193.3). IMH in the absence of PAU appears to follow a more stable course, especially when located in the descending thoracic aorta [63].
Etiology and Pathophysiology

There are two proposed mechanisms by which an IMH may form. The first is the rupture of the vasa vasorum in the aortic wall, which may be the result of medial degeneration. The other leading mechanism is the invasion of a PAU beyond the internal elastic lamina of the vessel, compromising the integrity of the media. Once in the media, this ulceration can lead to hematoma formation. Both of these events could ostensibly be at work simultaneously.

Clinical Manifestations

The clinical presentation of IMH mirrors that of typical aortic dissection, and the two cannot be reliably distinguished on the basis of clinical criteria alone.

Imaging

Because the clinical presentation of IMH can overlap with that of classic dissection, prompt imaging is critical. The same set of imaging modalities used for classic aortic dissection is to be used to image IMH.

CXR findings associated with IMH mirror those for classic aortic dissection. Affected patients may exhibit an abnormal aortic silhouette or a widened mediastinum, but this finding is not as well validated as in classic dissection. Separation of intimal calcium from the aortic border may also be visible. These are simply associated findings; differentiation of IMH from classic dissection requires other imaging modalities.

TTE does not allow for definitive, reliable diagnosis of IMH. With TEE,
IMH may appear as an echogenic, crescent-shaped segment of aortic wall. This is not a definitive modality, as in some cases, the thickened wall segment can be difficult to distinguish from atherosclerotic thickening.

With CT scanning, IMH appears as a crescent-shaped thickening of the aortic wall, but with a normal-appearing aortic lumen. CT imaging with and without contrast facilitates diagnosis as the hematoma has a higher tissue density than unenhanced blood on noncontrast CT but is without enhancement after contrast administration [1]. A contrast study is required for a definitive diagnosis. The most important feature that distinguishes an IMH from a classic dissection is the absence of contrast within the aortic wall. MRI allows for diagnosis of IMH without the use of contrast. The intensity of the hematoma can be determined by the signal sequence. Aortography is not a useful method for evaluating IMH, as the sensitivity for identification of IMH is less than 20%.

Management

As is the case for management of typical dissection, early imaging and surgical consultation are the central components of the management of a patient with an IMH, which can be a rapidly progressive disease. Frequent re-evaluation of the diseased aortic segment may also be warranted, especially if the patient presents with new hypotension or progressive symptoms. The most dangerous consequence of IMH is continued expansion and progression to typical dissection and/or aortic rupture. Given the high-risk nature of IMH in the ascending aorta, management is similar to typical aortic dissection: surgery for Type A syndromes and medical management for Type B syndromes [1,2]. The recent literature contains some controversy regarding the optimal management of acute Type A IMH [97,100].

For Type B IMH, medical management appears to be the consistently validated early treatment approach, unless a surgical indication is present. In-hospital mortality for patients in the IRAD series is less than 10% for patients receiving medical management.

There may be a role for prophylactic endovascular stent placement for patients with IMH who are thought to be in imminent danger of hematoma expansion and aortic rupture [101]. Type B IMH should be frequently reassessed and reimaged as indicated, as these patients are at increased risk for evolution into classical dissection or rupture. Several studies have suggested that a small proportion of IMH will resorb in short-term follow-up, and this appears to be correlated with smaller aneurysm size at presentation. However, a significant proportion of patients will go on to develop enlarging aortic aneurysm and/or pseudoaneurysm, classic aortic dissection, or rupture. The role of endovascular stents is evolving similar to that for Type B dissection [101].
The use of endovascular stent grafting to manage a complication of a Type B IMH with subsequent dissection is demonstrated in Figure 193.4. A summary of recommended management strategies for patients with acute aortic dissection or IMH is shown in Figure 193.5.
A–C: Endovascular aortic stent grafts for nonsurgical management of Stanford Type B dissection. This patient initially presented with acute Type B dissecting intramural hematoma. A: shows a contrast-enhanced (CT) scan of the chest demonstrating acute intramural hematoma just inferior to the pulmonary artery bifurcation with a circumferential, crescentic appearance (H). The IMH extended from just distal to the takeoff of the left subclavian artery down to the level of the celiac axis. B: shows evidence of active hemorrhage into the aortic media (M) at the proximal descending thoracic aorta. C: shows a follow-up contrast-enhanced chest CT of the same patient at 36 days after initial presentation, with evidence of evolution of the IMH into a classic dissection, with true lumen (T) and filling of the false lumen at the same level in the proximal descending aorta as shown in A. D–F: D: shows the contrast-
enhanced chest CT scan after placement of a stent graft (S) in the proximal descending aorta at the site of presumed communication between false and true lumen, demonstrating complete exclusion of the hematoma. E: demonstrates a three-dimensional reconstruction of the contrast-enhanced CT scan of the aorta in the left anterior oblique view of the same patient 36 days after initial presentation with extravasation of contrast (C) (corresponding to the image in C), and F: shows the same left anterior oblique view of the aorta status-post endovascular stent grafting procedure (S, stent).

FIGURE 193.5 A suggested management strategy for patients with suspected acute aortic syndrome.

Although experience has varied, management of IMH should proceed according to the principles outlined for classic dissection. Specifically, patients with Type A IMH should receive surgery. The natural history of Type B IMH has been well delineated. Some may resorb spontaneously, while others go on to evolve classic dissection, false aneurysm, or true aneurysm formation.
EXPANDING AORTIC ANEURYSM AND RUPTURE

Definition and Classification

An aortic aneurysm is broadly defined as a segment of the aortic lumen whose diameter exceeds 1.5 times the normal diameter for that segment [1]. The risk of aneurysm rupture increases as a function of diameter. In addition, rupture risk is thought to be higher for rapidly expanding aneurysms. Aneurysms are also classified according to location (e.g., thoracic vs. abdominal), morphology, and etiology. All segments of the aorta can be affected and multiple aneurysms may be found in a single patient. Up to 13% of patients with an identified aortic aneurysm are found to have multiple aneurysms; as such, for patients in whom a single aneurysm has been detected, consideration should be given to scanning the entire aorta for additional aneurysms. In the general population, abdominal aneurysms are more common than thoracic aneurysms. Overall, aortic aneurysm is the eighth leading cause of cardiovascular mortality and was estimated to have caused more than 150,000 deaths globally in 2013.

The most commonly encountered aortic aneurysm morphology is fusiform—specifically, a symmetrical dilatation of an aortic segment, involving the entire circumference of the vessel wall (Fig.193.6). Aneurysms may also be saccular, or may involve only a portion of the vessel, leading to an asymmetric dilatation. It is also important to distinguish between true and false aneurysms: a true aneurysm involves all three layers of the vessel wall, whereas a false aneurysm is typically a collection of blood underneath the adventitia or outside the vessel altogether. This collection is frequently the result of a defect in the aortic wall. The presence of a suspected saccular aneurysm deserves special note, as it may actually represent a false aneurysm caused by a partially contained rupture of the aortic wall.
Aortic aneurysms are frequently asymptomatic at the time of diagnosis, and tend to be detected with tests ordered for other reasons. Indeed, an aortic aneurysm may not be associated with any symptoms until the time of rupture. As the clinical presentations of ruptured thoracic and abdominal aortic aneurysms (AAAs) frequently differ, they are discussed separately.
ANEURYSMS OF THE THORACIC AORTA

Epidemiology

The overall annual incidence of thoracic aortic aneurysm (TAA) is 6 per 100,000, and up to 40% of all patients are asymptomatic at the time of diagnosis. The risk of aneurysm rupture or dissection increases as a function of size. An abrupt increase in risk has been noted at a diameter of 6 cm: for aneurysms greater than 6 cm, the rupture rate has been observed to be 3.7% per year [1]. The most commonly affected segments are the aortic root and ascending aorta; 60% of observed cases involve these segments. Aneurysms of the descending aorta account for 40% of cases, and the aortic arch accounts for 10%.

The surgical treatment strategy for asymptomatic aortic aneurysms differs on the basis of location, size, and etiology: for an aneurysm of the aortic root or the ascending aorta, surgical repair is indicated for a diameter of 5.5 cm or more or for aneurysms expanding at a rate >0.5 cm per year [1]. Patients who by nature of their underlying disease state are at increased risk of rupture, such as patients with Marfan syndrome, 5 cm (or less in certain cases, such as in patients with strong family histories for premature aortic dissection or rupture) is the recommended operative threshold [102]. For patients with aneurysm in the setting of bicuspid aortic valve the rate of dissection or rupture at diameters below 5.0 cm is low and a recent consensus statement suggested that using 5.5 cm was reasonable although treatment at lower dimensions should be considered if expanding rapidly or if valve surgery was warranted [103]. Endovascular aortic repair with aortic arch vessel revascularization has been described and may be an option in the future for patients at heightened surgical risk [104]. In the descending thoracic aorta, size remains the principal predictor of adverse outcomes with low rates of complications at sizes below 5.0 to 5.5 cm [105].

For patients with large TAAs, survival without surgical repair is poor, with 5-year survival after initial identification at 20%. Rupture occurs in 32% to 68% of patients whose TAAs are not repaired surgically [1]. Of those patients whose rupture occurs outside a hospital setting, it is thought that less than half will arrive to a hospital alive. For those patients who survive until hospital admission, mortality at 6 hours is 54%. At 24 hours, mortality without surgery is 76%.
Etiology and Pathophysiology

Multiple factors have been implicated for the formation of TAAs, including atherosclerotic disease, specific gene defects, and infectious processes. In many cases, a central pathophysiologic process is medial degeneration, which leads to the loss of elastic fibers and smooth muscle cells. This process, which is frequently correlated with aging, causes progressive stiffening and weakening of the vessel wall, leading to progressive dilatation. Hypertension accelerates dilatation due to the increase of wall strain.

The inciting factors that lead to aneurysm formation influences which portion of the aorta is affected and the age at which the abnormality tends to be diagnosed. Aneurysms of the aortic root and ascending aorta are frequently associated with inherited defects of structural genes or with inflammation caused either by infection or by vasculitis. In general, aneurysms associated with structural genetic mutations tend to occur at a younger age, in some cases during the second and third decades of life [25]. Identified connective tissue disorders, such as Marfan and Ehlers–Danlos syndromes, have been established as causes for aneurysms of this portion of the aorta [25]. These syndromes are caused by deficits in fibrillin-1 and type III collagen, respectively [25]. In addition, mutations of transforming growth factor beta (TGF-β) signaling have been associated with aneurysm and dissection [24]. Mutations in LRP1, LOX, FBN1, ULK4, ACTA2, SMAD1, the X-linked biglycan gene, and other genes have all been described in the setting of dissection [26,27,106–108]. The specific protein deficits lead to weakening of the vessel wall due to medial necrosis with resultant ectasia. A growing body of evidence reveals a hereditary syndrome (FTAAS) that does not lead to overt manifestations of connective tissue disease but is associated with aneurysm of the ascending aorta. Multiple loci have been identified, but routine genetic testing for this spectrum of disorders is not yet available. A bicuspid aortic valve is also associated with aneurysm of the aortic root/ascending aorta [109–111]. Dilation of this segment of the aorta has been shown to be due to medial degeneration that is independent of the potential hemodynamic effects of the abnormal valve. An acquired defect of the integrity of fibrillin-1 may also occur in some of these patients. A growing body of evidence suggests that the enzymatic activity of several matrix metalloproteinases (MMPs) may play a central role in the loss of connective tissue integrity for patients with bicuspid aortic valve [112]. Turner syndrome is associated with an increased incidence of bicuspid
aortic valve, as well as with aortic coarctation and aneurysm of the ascending aorta [25].

Ascending aortic aneurysm may also be caused by infectious processes, such as bacterial endaortitis or chronic spirochetal infection. Syphilis, once a common cause of aneurysm in the ascending aorta but less frequently dissection, is now rarely seen in the developed world. The aortitis caused by bacterial infection leads to both fusiform and saccular aneurysms. Inflammation-related aneurysm in this area may also be caused by vasculitic processes, most notably Takayasu or giant cell arteritis. Although typically associated with stenotic lesions of the aorta or great vessels, Takayasu arteritis may present acutely, with the development of aortic aneurysms that are associated with signs of systemic and focal aortic inflammation; in rare cases, patients with acute aortic dilatation associated with Takayasu arteritis have suffered acute aortic rupture. Patients with Takayasu arteritis are typically younger Asian females, who may show involvement of the pulmonary arteries as well. In contrast, aneurysms associated with giant cell arteritis are more frequently diagnosed in older Caucasian females with prior polymyalgia rheumatica and/or symptomatic temporal arteritis.

Aneurysms of the descending aorta are generally caused by atherosclerosis. As such, these aneurysms are more commonly found in men and are not frequently seen before the sixth decade of life. These aneurysms are found beyond the branch point of the left subclavian artery and are typically fusiform. Saccular aneurysms may be found at the aortic isthmus, and are frequently the result of rapid deceleration trauma.

Clinical Manifestations

Expanding aneurysms of the ascending and descending thoracic aorta produce symptoms due to compression of neighboring thoracic structures and compromise of aortic valve function (see later in the chapter). Compression leads to chest and back pain in as many as 37% and 21% of cases, respectively. Specific thoracic structures, when compressed by the aorta, lead to distinct signs and symptoms, including superior vena cava syndrome, pulmonary symptoms due to tracheal compression, or dysphagia due to esophageal compression. In addition, stretching of the recurrent laryngeal nerve may lead to unilateral vocal cord paralysis, with hoarseness (Ortner syndrome).

Symptoms from rupture of a TAA are largely related to mechanical effects of blood extending into adjoining thoracic spaces. The sudden onset of acute chest or back pain is a common feature of aneurysm
rupture for all segments of the thoracic aorta. Perhaps the most salient feature of this pain is the fact that its maximal intensity occurs at onset. In patients whose aneurysms have produced prior symptoms, the pain at the time of rupture may be a more intense form of the same sensation, often at the same location. The pain does not necessarily have a tearing quality, as is often the case with dissection.

The most common area of blood flow from a rupture of the ascending aorta is the left pleural space, followed by the intrapericardial space. Blood flow into these areas lead to hemothorax and hemopericardium. Tamponade physiology may be present. Rupture of the descending aorta can lead to erosion into the esophagus: over time, an aortoesophageal fistula may form, leading to severe hematemesis. No matter where the point of blood egress is found, rapid loss of intravascular volume leads promptly to hypotension and shock if unrepaired. Ancillary warning signs include decreased urine output and altered mental status.

The heart examination may also exhibit distinct abnormalities with expanding aneurysm and rupture. Progressive dilatation of the aortic root may lead to dilatation of the valve annulus with consequent signs of aortic regurgitation. This phenomenon is associated with a diastolic murmur heard best over the left sternal border with the exception of aneurysms associated with ectasia of the aortic root, such as syphilitic aortitis, where the murmur of aortic regurgitation may be more noticeable along the right sternal border. Critical levels of regurgitation may be associated with left-sided heart failure. This murmur may be present in the absence of rupture. When rupture of one of the sinuses of Valsalva occurs, the murmur may be continuous; in this setting, the ruptured area may communicate with a cardiac chamber, such as the right atrium or ventricle.

In the context of acute rupture, the electrocardiography frequently shows evidence of ventricular “strain” or ischemia. Over time, markers of myocardial necrosis may be elevated as well. Several studies show an elevation of D-dimer in the context of aortic dissection, but elevation of this marker has not yet been validated for aneurysm progression or rupture [104]. There is currently no widely available biomarker in use to detect vascular injury in the context of aneurysm or rupture.

Imaging

Aortic aneurysm may be visualized as a widened mediastinum on anteroposterior views. Although this technique offers invaluable information, it cannot be considered a definitive study. TTE allows for the evaluation of the aortic root and ascending aorta. TEE is well suited to the evaluation of potentially aneurysmal segments in the aortic arch and descending aorta. As noted previously, perhaps the most important
procedural drawback regarding TEE is the need for conscious sedation, which may be difficult to administer to a patient who is hemodynamically unstable.

CT scanning allows for evaluation of potentially aneurysmal segments in the entire aorta. Contrast CT imaging may also be helpful in identification of areas of blood extravasation in ruptured aortic aneurysms. MRI may be used for aortic measurement and identification of aneurysmal segments without contrast. Evaluation of blood extravasation with MRI is possible, but thought to be less sensitive than CT with contrast, especially for slow or low-volume extravasation. Aortography is a highly sensitive technique for assessing extravasation. The use of this technique in the acute setting is ordinarily reserved for those cases where neither CT scanning nor MRI is available.

Rupture of a Thoracic Aortic Aneurysm: Management

Rupture of a TAA is a surgical emergency. Open repair of the vessel is the most established repair technique. Typically, the procedure is performed with deep hypothermic circulatory arrest. The type of repair is determined by the location of the rupture and the presence or absence of aortic valve involvement. Dacron grafts are generally placed to replace the diseased vessel segment, with various strategies for aortic valve repair or replacement when necessary. Recent work indicates that a less invasive form of repair, retrograde endovascular stent placement, may be useful for the repair of aneurysms of the descending aorta.

Patients with aneurysm of both ascending and descending segments present an additional challenge. Standard methods entail surgical replacement of diseased segments in a “staged” fashion; however, newer methods involving a hybrid approach of surgical replacement of the ascending aorta, with subsequent endovascular therapy of the distal segments, appear promising.

It may be that a particular patient presents with complaints raising concern for a ruptured aortic aneurysm. In the event that no rupture is found and the patient is hemodynamically stable, it is possible that expansion of the aneurysm is responsible for the symptoms. In such a case, the focus of immediate clinical treatment should be to decrease aortic wall strain and systemic blood pressure through the use of β-blockers in the context of a critical care setting. Prompt surgical consultation plays a vital role in the continuing care of these patients.
ANEURYSMS OF THE ABDOMINAL AORTA

Epidemiology

AAAs are far more common than TAAs. The estimated prevalence of AAAs ranges between 1.3% and 8.9% in men and between 1.0% and 2.2% in women older than 60 years. Most cases are observed in men older than 55 years and women older than 70 years. AAAs have been found to be correlated with smoking. Overall prevalence of abdominal aneurysms has risen substantially over the past 30 years. This trend has been linked to the increased prevalence of atherosclerosis, which is thought to be the major etiology responsible for abdominal aneurysms. In addition, improvements in imaging technology have increased the rate of detection.

Rupture of AAAs is estimated to cause approximately 15,000 deaths per year in the United States. The total mortality rate for patients with rupture ranges from 65% to 85%. One prospective study revealed that 25% of patients with AAA rupture die before arriving at a hospital. Of those who arrived at the hospital alive, 51% died before surgery. Patients who did have surgery sustained a 46% operative mortality rate. Total 30-day survival rate for this population was 11%. Given the poor prognosis associated with rupture, elective repair is recommended when possible. As is the case with TAAs, the risk of rupture increases as a function of aortic diameter.

Etiology and Pathophysiology

Incidence of AAA is closely correlated with the presence of atherosclerotic disease in the aorta. In general, the infrarenal segment of the aorta is most heavily affected by atherosclerosis, and this is also the segment where most abdominal aneurysms are observed. These aneurysms are typically fusiform, but saccular aneurysms may also be found.

The risk factor most closely associated with abdominal aneurysms is smoking, followed by age, hypertension, and hyperlipidemia. There is also a strong association between gender and abdominal aneurysm formation. Family history of AAA is associated with a 30% increase of risk for AAA formation, but there are not yet any specific genes linked with this finding.

Damage to the vessel wall, caused by atherosclerotic plaque, has been
shown to cause local inflammation. This inflammatory process is thought to cause degradation of extracellular matrix proteins, notably elastin and collagen. In addition, it is thought that the proinflammatory cytokine milieu leads to cell death within the vessel wall. Weakening of the vessel wall follows, potentially accelerated by the action of multiple proteases, including MMP and cathepsin L [112]. There is some speculation that MMP polymorphisms may lead to a change in susceptibility to abdominal aneurysms, but there are no screening tests currently available to the clinician [112]. Hypertension increases the wall strain on the weakened vessel wall, leading to accelerated expansion. The full effects of smoking on aneurysm formation and expansion are not known, but increased atherosclerosis and hypertension are thought to be contributors.

Aneurysms of the descending thoracic aorta tend to be caused by atherosclerosis. These aneurysms often extend into the abdominal cavity, superior to the renal arteries. Such aneurysms are referred to as thoracoabdominal, and their management mirrors the management of aneurysms in the abdominal cavity.

Aneurysms of the descending thoracic or abdominal aorta may also be caused by acute bacterial infections. This is not a common finding, but tends to be found more often in patients who are IV drug users or who have traveled recently from a country where exposure to typical organisms (Salmonella and Brucella) is more likely to occur. Chronic tuberculosis is rarely associated with abdominal aneurysms. Syphilis may also be associated with abdominal aneurysms, but it is more commonly associated with the ascending aorta. Connective tissue disorders, such as Marfan and Ehlers–Danlos syndromes, do not typically affect the abdominal aorta; however, some systemic inflammatory disorders, notably Takayasu arteritis or Behcet disease, may be associated with abdominal aneurysms.

Clinical Manifestations

As is the case with thoracic aneurysms, most abdominal aneurysms are asymptomatic and tend to be discovered with testing performed for other reasons. Those patients who do have aneurysm-related complaints tend to report pain in the hypogastric area and/or pain in the lower back. This pain is caused by the expansion of the aneurysm and tends to last for hours or days at a time, and is usually dull and steady. In the abdomen, fewer structures tend to be affected by the expanding aorta. The most common consequence of aortic expansion is compression of the ureter or kidney, leading to hydronephrosis.

An episode of rupture tends to be announced by a sudden onset or increase in abdominal and/or back pain. The most notable feature of this pain is that it is at its maximum at the time of onset. Rupture most
frequently leads to blood leakage into the left retroperitoneal space. These patients may present with an initial episode of pain associated with the first rupture, followed by temporary tamponade of the retroperitoneal space. A larger, life-threatening bleed inevitably follows. Less frequently, the aneurysm may erode into surrounding structures, most notably the duodenum, leading to either formation of an aortoduodenal fistula or potentially massive gastrointestinal (GI) bleeding.

Physical examination of a patient with an AAA may reveal a palpable, pulsatile mass in the midline. This mass is easiest to palpate in the hypogastric or paraumbilical region. The sensitivity of the manual examination is suboptimal: 82% for aneurysms 5 cm or greater. Furthermore, a mass may be difficult to appreciate. Consequently, the absence of a pulsatile mass on physical examination should not be interpreted as an absence of aneurysm. On rupture of an abdominal aneurysm, most patients become hypotensive, tachycardic, and diaphoretic. Patients may also exhibit signs of peritoneal irritation on examination. As noted, the patient may also present with evidence of GI bleeding. Laboratory analysis may reveal evidence of elevation in D-dimer or an elevation in cardiac biomarkers, due to demand-related myocardial ischemia. The incidence of popliteal aneurysm is higher among patients with AAA so a careful popliteal pulse examination should be performed with ultrasound imaging where abnormal.

Imaging

Transcutaneous ultrasound is a noninvasive and readily available technique for the evaluation of the abdominal aorta. This method is frequently used to track the size of abdominal aneurysms, though it is not the imaging modality of choice for the acute aortic syndromes. Like TTE, abdominal ultrasound is often limited by body habitus. As with thoracic aneurysms, the most definitive evaluations are provided by CT scanning and MRI. Aortography may provide useful information regarding aortic aneurysm, but it is not the modality of choice in the acute setting unless CT scanning and MRI are not available.

Rupture of an Abdominal Aortic Aneurysm: Management

Rupture of an AAA is a surgical emergency. Open repair, with replacement of the diseased segment with a Dacron graft, is the most established technique. Intraoperative mortality after rupture is very high, as noted previously. Retrograde endovascular stent placement is a promising technique [113–115], but it is not yet in common use in the acute setting [116,117]. Timely, but elective, surgical or endovascular
intervention on the basis of size criteria, as assessed with longitudinal imaging, is the most effective means to prevent progression to rupture.
REFERENCES

DEFINITION/EPIDEMIOLOGY

Acute decompensated heart failure (ADHF) is the most common indication for hospitalization in the USA and results in nearly 1 million hospitalizations annually [1]. In-hospital mortality for all patients in the Acute Decompensated Heart Failure National Registry (ADHERE) averaged 4% but was substantially higher in the cohort of patients over 75 years of age [2]. Potential explanations for the higher prevalence of heart failure in the elderly include the high rate of hypertension; ventricular remodeling from prior myocardial infarction; age-related loss of functional myocytes; and increased extracellular matrix that contributes to alterations in left ventricular compliance. Several of these features combine to create a ventricular phenotype of “heart failure with preserved ejection fraction.” Thus, 40% to 50% of heart failure admissions in the elderly occur in the setting of preserved systolic function; however, these episodes carry the same in-hospital mortality rate. Indications for hospitalization for patients with ADHF have been summarized by the Heart Failure Society of America in their Practice Guidelines (Table 194.1) [3].

| TABLE 194.1 Indication for Hospitalization in Acute Decompensated Heart Failure |
|---------------------------------|---------------------------------------------------------------|
| Definite                        | Evidence for severe decompensation with:                     |
|                                 | Hypotension                                                  |
|                                 | Worsening renal function or oliguria                        |
|                                 | Mental obtundation                                           |
|                                 | Dysepsnea at rest (resting tachypnea; oxygen                 |
Most (>70%) acute heart failure admissions occur among patients with chronic heart failure. The differentiation of new-onset decompensated heart failure from subacute or acute worsening of chronic heart failure is important, because their pathophysiologies differ. Patients with new-onset heart failure have intense sympathetic activation and enhanced microvascular permeability [4]. Consequently, jugular venous distention may be more difficult to assess in these patients because of venous vasoconstriction and redistribution of fluids. Over 60% of patients hospitalized with ADHF have a history of coronary artery disease, hypertension, atrial fibrillation, diabetes mellitus, or renal dysfunction. Although dramatic, only 5% to 10% of patients with acute decompensation present with “sudden-onset” pulmonary edema.

Pathophysiologic Considerations

A variety of pathophysiologic mechanisms may be responsible for an ADHF episode. The key feature is volume overload with pulmonary and/or venous congestion. Hemodynamic measurements typically reveal increased right- and left-sided ventricular filling pressures; cardiac index is often, but not always, depressed. Congestion may be related to poor adherence to diet or medications or progression of left ventricular dysfunction with concomitant activation of vasoconstrictor neurohormones and/or worsening renal function. Other comorbidities, particularly poorly controlled hypertension, new onset atrial fibrillation, or active myocardial ischemia may also contribute to acute decompensation.
Deterioration of renal function may result from diminished cardiac output and a corresponding reduction of glomerular filtration rate, high venous filling pressures, intra-renal vasoregulation, alterations of circulatory volume, more intense neurohormonal activation, and/or the nephrotoxic effects of medications administered during hospitalization. Angiotensin II actively induces secretion of endothelin-1 and vasopressin. Further elevation of these neurohormones leads to sodium and water retention, increased myocardial wall stress, and decreased renal perfusion. A deleterious positive feedback loop is often established resulting in chronic elevation of vasoconstrictor neurohormones and worsening heart failure [1].

Myocardial injury is now recognized as an important element of the ADHF syndrome [5–7]. Myocyte loss is triggered by subendocardial myocardial ischemia, myocardial strain (consequent to elevated filling pressures), neurohormonal activation (via angiotensin II, endothelin, and aldosterone), systemic inflammation, and oxidative stresses [1]. Strategies aimed at preventing or limiting acute myocardial injury should be considered a treatment goal during management of any acute episode.

Predictors of Prognosis

Patients hospitalized for ADHF have a 2.5-fold higher 4 year mortality than that observed for stable chronic heart failure patients (60% versus 15%) [2]. Findings on physical examination also predict prognosis and should influence treatment during hospitalization. The presence of a chronic third heart sound or elevation in jugular venous pressure establish more advanced disease and predict increased long-term mortality. Moderate-to-severe mitral or tricuspid regurgitation are also both associated with increased symptoms, morbidity and mortality.

Table 194.2 lists independent parameters that have been correlated with clinical outcomes of hospitalized heart failure patients. These parameters include older age, male sex, heart failure etiology, history of previous heart failure hospitalization, respiratory rate, anemia, comorbid conditions, and biomarker levels. The utility of biomarkers, particularly B-type natriuretic peptide (BNP), NT-pro BNP and ST2, have been shown useful in identifying patients at increased risk for readmission or deaths [8]. Serial assessment of BNP during hospitalization is useful for predicting post-discharge prognosis and suggests that this approach may soon help guide heart failure inpatient management. However, it should be recognized that a variety of etiologies including pulmonary embolism, acute coronary syndromes, and sepsis may also lead to markedly elevated BNP. Troponin I or T release occurs in 30% to 70% of ADHF patients; its elevation is associated with a twofold increase in post-discharge mortality and a threefold increase of rehospitalization rates [6,7]. Further, the
combination of elevated BNP and troponin has been associated with a 12-fold increased risk of mortality. Several studies have demonstrated lower systolic blood pressure, higher blood urea nitrogen, and severity of hyponatremia as independent predictors of in-hospital mortality [9]. Renal dysfunction is also recognized as an extremely powerful predictor of heart failure outcome. The presence of chronic renal insufficiency, defined as a serum creatinine >1.4 mg per dL for women and >1.5 mg per dL for men, predicts an increased risk of death (risk ratio = 1.43). Unfortunately, approximately 25% of hospitalized patients with decompensated heart failure will exhibit a deterioration of renal function despite appropriate medical therapy. In these hospitalized patients, a modest rise in serum creatinine (i.e., 0.30 to 0.5 mg per dL) has been associated with a longer length of hospital stay and increased in-hospital mortality in some but not all series. This constellation of poorly understood physiologic mechanisms has been termed the “cardiorenal syndrome” and its optimal management remains to be defined [10].

Fonarow et al, using ADHERE data on over 33,000 patients, performed an extensive risk stratification of in-hospital mortality during ADHF [2]. Recursive partitioning of 32 key variables indicated that the best single predictor of in-hospital mortality was a high admission level of blood urea nitrogen (>43 mg per dL), followed by admission systolic blood pressure <115 mm Hg and a serum creatinine >2.75 mL per dL. On the basis of these three simple variables, patients can be readily stratified into groups at low, medium, and high risk for in-hospital mortality with rates ranging from 2.1% to 21.9%. Additional predictive variables from other studies include troponin release, markedly elevated natriuretic peptide levels, hyponatremia, and pulmonary hypertension [8,11]. Early identification of high-risk patients may ultimately lead to better strategies designed to improve their in-hospital outcomes.
PHARMACOLOGIC MANAGEMENT OF ADVANCED HEART FAILURE

Congestion is the most common cause for admission for ADHF and should be aggressive treated with diuretics. Renal function will often worsen transiently during aggressive in-hospital diuresis. Although earlier studies suggested increased mortality for modest increases of serum creatinine (e.g., >0.3 mg per dL), recent findings by Metra et al. and Testani et al. have shown that persistent congestion due to inadequate diuresis rather than transient changes of renal function greatly increases the risk of adverse outcomes following hospital discharge [12,13]. The importance of this finding is that diuresis should not be curtailed during ADHF treatment because of a modest decline of baseline renal function.

Almost 50% will have heart failure with preserved ejection fraction rather than systolic dysfunction. The acute treatment for volume overload should not differ by etiology. The treatment of HF-pEF is largely empirical as clinical trials have failed to find effective therapies to improve prognosis. The goals of medical therapy in HF-pEF should include adequate control of hypertension, rate control or restoration of normal sinus rhythm for new onset atrial fibrillation, and evaluation and management of myocardial ischemia or valvular heart disease. The remaining sections discuss treatment of heart failure with reduced ejection fraction (HF-rEF).

Systolic heart failure that persists after correction of potentially reversible causes (Table 194.3) should be treated with dietary sodium restriction, diuretics for volume overload, vasodilator therapy (particularly ACE inhibitors or angiotensin receptor antagonists), and a \( \beta \)-adrenergic blocker [14]. Sodium restriction (<4 g per day) is generally indicated for patients with advanced symptoms. Likewise, many ADHF patients require a 1.5 to 2 L per day fluid restriction.

Diuretics

Diuretics remain the mainstay for “congestive symptoms” but have not been shown to improve survival during hospitalization or long-term treatment. Neurohormonal activation (as measured by circulating renin, angiotensin II, endothelin-1, and BNP) has been shown to acutely decrease during short-term diuretic therapy administered to lower markedly elevated filling pressures. Two pharmacologic classes of agents are relevant to acute heart failure management: loop diuretics and distal tubular agents (Table 194.4). Loop diuretics (e.g., furosemide, torsemide, bumetanide, and ethacrynic acid) are the most potent. Some data suggest that oral torsemide and bumetanide may be more effective than furosemide for advanced heart failure, perhaps because of superior absorption from the gastrointestinal tract in the setting of elevated right-sided filling pressures. Although once daily dosing of loop diuretic is usually effective for outpatient therapy, patients with persistent symptoms or those with marked hemodynamic instability during hospitalization often require dosing two or three times a day to adequately manage volume overload.

mg, milligrams; IV, intravenous.

Thiazide diuretics such as hydrochlorothiazide and metolazone act mainly by inhibiting reabsorption of sodium and chloride in the distal convoluted tubules of the kidneys. Thiazides produce a fairly modest diuresis; however, these agents are ineffective when glomerular filtration rate (GFR) falls below 40 mL per minute.

Diuretic tolerance is often encountered in ADHF patients. Lack of response to diuretic therapy may be caused by excessive sodium intake; use of agents that antagonize their effects (particularly nonsteroidal anti-inflammatory drugs); worsening renal dysfunction; addition of potentially nephrotoxic agents during hospitalization; or compromised renal blood flow due to worsening cardiac function. Combined intravenous loop diuretic plus thiazide creates a synergistic response and should be considered for patients who fail to diurese despite optimal doses of an intravenous loop diuretic alone [15]. Metolazone is particularly effective when administered with a loop diuretic.

Two recent randomized controlled trials have evaluated various diuretic dosing strategies in ADHF. The DOSE-HF trial demonstrated that there were no significant differences in patient global assessment of
symptoms, or in renal function when loop diuretics were administered by intermittent boluses compared to continuous infusion [16]. Similarly, high-dose loop diuretics did not improve dyspnea more quickly than low-dose intravenous diuretics [16]. In a second study, neither low-dose (“renal”) dopamine nor low-dose nesiritide increased urine output at 72 hours compared to loop diuretics alone [17]. Finally, high-dose diuretics, when needed, have not been shown to produce greater activation of the renin–angiotensin–aldosterone system (RAAS) than low-dose diuretics [18].

Elevated vasopressin levels play an important role for mediating fluid retention and contributing to hyponatremia. Short-term treatment with the V2-receptor antagonist, tolvaptan, has been shown to lower filling pressures, enhance diuresis, correct hyponatremia, and improve renal function. Ongoing trials are evaluating the role of vaptan therapy in ADHF management.

Ultrafiltration (UF) using a venovenous access approach is now feasible and potentially useful for acutely lowering markedly elevated ventricular filling pressures when conventional high-dose combination diuretic therapy fails to produce adequate diuresis. Contrary to initial suggestions, UF has not been shown to produce less activation of the RAAS than loop diuretic therapy [18]. Small, short-term observational studies suggested increased weight loss during hospitalization but have not demonstrated decreased length of stay or better preservation of renal function. The UNLOAD trial randomized 200 patients with ADHF to standard intravenous diuretics versus UF and demonstrated greater weight loss at 48 hours in the UF cohort [19]. Readmissions for heart failure were also lower at 90 days (32% versus 18%) for the UF group. However, no comment was made on overall rehospitalization rates and renal function was not improved. A recent randomized controlled trial for ADHF with worsening renal function demonstrated that UF resulted in an identical degree of weight loss, but worse renal function and more adverse events than standard loop diuretic therapy [20]. Despite early hopes, UF does not improve renal function; in fact, worsening renal function occurs quite frequently during UF and is associated with an extraordinarily high 1-year mortality [21]. Importantly, hemodynamic instability has been an exclusion criterion in all published studies. The latest ACC/AHA practice guidelines recommend ultrafiltration as a class IIa therapeutic option for heart failure that remains refractory to conventional diuretic therapy [14]. Several ongoing controlled trials should better define the therapeutic niche for this treatment modality.

**Vasodilator Therapy**

Vasodilators remain a cornerstone of acute and chronic heart failure
management (Table 194.5) [22,23]. Mechanisms of action vary and include direct effects on venous capacitance vessels (e.g., nitrates), arterioles (e.g., hydralazine), or balanced effects (sodium nitroprusside, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin II receptor blockers). Drugs that produce balanced venous and arteriolar dilatation should generally be chosen as a first-line therapy because both preload and afterload are elevated during ADHF. However, in the ICU setting, it may sometimes be useful to use nitrates to reduce markedly elevated preload or hydralazine to treat elevated afterload for short periods of time. ACE inhibitors play a crucial role by altering the vicious cycle of hemodynamic abnormalities and neurohormonal activation that characterize advanced heart failure [23]. Randomized, controlled clinical trials have demonstrated the beneficial effects of ACE inhibitors on functional capacity; neurohormonal activation; quality of life; and long-term survival for patients with chronic heart failure due to left ventricular systolic dysfunction [23]. There is compelling evidence that ACE inhibitor therapy should be continued whenever feasible for all ADHF patients [14,23]. It is especially important to recognize that for patients with advanced heart failure that even low doses of vasodilator treatment confer benefits. Low-dose treatment should be considered for patients with marginal blood pressure (i.e., systolic pressure >85 to 90 mm Hg) in order to permit the subsequent introduction of β-blockers. An ACE inhibitor should be initiated for any patient who experiences a transmural myocardial infarction during hospitalization, because post-infarction trials have shown 10% to 27% reductions in all-cause mortality and 20% to 50% reductions in the risk of developing overt heart failure.

**mg, milligrams.**

Alternative therapy with combination hydralazine and nitrates should be considered for patients with marginal renal function (creatinine >2.5 mg per dL) and those with previously documented intolerance to ACE inhibitors or angiotensin receptor blockers [14]. Similar hemodynamic goals can be achieved with these agents among patients with advanced NYHA Class III or IV heart failure. Women appear somewhat less responsive to ACE inhibitor therapy than do men. Important racial differences may also exist in pharmacologic responsiveness to different vasodilator regimens. Two retrospective analyses from large trials confirmed ACE inhibitor therapy to be less effective in blacks than whites with heart failure of comparable severity. The African-American Heart Failure trial (A-HeFT) confirmed the benefit of hydralazine and isosorbide dinitrate for this population; this combination should be considered when initiating therapy for hospitalized black patients [14, 23].

Angiotensin receptor blockers (ARBs) are now also considered a suitable first-line therapy for heart failure patients [14]. These drugs should be selected for ACE inhibitor–intolerant, non–African-American
patients who experience rash or cough with an ACE inhibitor. They cannot be used for patients who experience ACE inhibitor-related deterioration in renal function, hypotension or hypokalemia. Symptomatic and mortality benefits appear comparable between ACE inhibitors and ARBs. Combination therapy with and ACE inhibitor and ARB has largely been replaced by the use of an aldosterone antagonist as third agent to go along with an ACE inhibitor and β-adrenergic blocker [14]. A novel drug that combines neprilysin inhibitor with an ARB (sacubitril-valsatan) has recently been shown superior to standard ACE inhibitor therapy for outpatient management [24]. It has not been studied in ADHF and should not be initiated during hospitalization.

Digitalis

Digoxin continues to have a role for the management of patients with advanced NYHA class III to IV symptoms [14]. The drug has mild positive inotropic effect on cardiac muscle, reduces activation of the sympathetic and renin angiotensin systems, and partially restores the favorable inhibitory effects of cardiac baroreceptor function [25]. Short- and long-term controlled trials have provided unequivocal evidence that chronic digoxin administration increases left ventricular ejection fraction, improves exercise capacity, decreases advanced heart failure symptoms, and reduces heart failure associated hospitalizations [25]. Post hoc analysis has shown that patients most likely to demonstrate a favorable response had severe symptoms, greater degrees of left ventricular dysfunction, lower ejection fractions, and the presence of a third heart sound. A prespecified subgroup analysis of patients enrolled in the Digitalis Investigation Group (DIG) trial provided confirmatory evidence that patients with severe heart failure (LVEF <25% or CT ratio >0.55) showed the greatest benefit [26]. Because renal function may fluctuate considerably during hospitalization, measurement of serum digoxin levels is important. Retrospective subgroup analysis has suggested an increased risk of all-cause mortality among both women and men who have digoxin levels >1.0 ng per dL [26]. Poor renal function, small lean body mass, and elderly patients are at greatest risk for developing digoxin toxicity during standard maintenance dosing. In addition, a number of commonly utilized drugs including verapamil, flecainide, spironolactone, and amiodarone will significantly increase serum digoxin levels. Recent data from the TREAT-AF study have suggested increased mortality rates of patients without heart failure who are treated with digoxin for rate control in new-onset atrial fibrillation [27]. In general, digoxin should be
not be used as a first-line therapy for rate control. For adult patients with advanced heart failure, sinus rhythm, and normal renal function, a dosage of 0.25 mg per day is appropriate. For patients at increased risk of toxicity, the initial starting dose should be 0.125 mg daily and uptitrated as necessary to achieve a trough level of 0.5 to 0.9 ng per dL.

**β-Adrenergic Blockers**

β-adrenergic blockers have been shown to lower all-cause mortality and decrease heart failure hospitalizations in a variety of randomized controlled trials in patients with NYHA class II to IV symptoms (Table 194.5) [14]. The mortality benefits of β-blocker therapy for patients with advanced (NYHA class IV) heart failure symptoms is clearly established [14]. The Carvedilol Perspective Randomized Cumulative Survival (COPERNICUS) trial evaluated patients with severe symptoms and LVEF < 25% [28]. Carvedilol reduced all-cause mortality by 35%, the combined risk of death or cardiovascular hospitalization by 27%, and the risk of death or heart failure hospitalization by 31% [28]. Importantly, carvedilol-treated patients spent 40% fewer days in the hospital for acute heart failure decompensation [28]. It appears that not all β-blockers have equivalent benefits for heart failure. For example, bucindolol, a third generation nonselective β-blocker with intrinsic sympathomimetic activity, was not associated with statistically significant reductions of overall mortality. Unlike ACE inhibitors or ARBs, the specific β-blockers (e.g., bisoprolol, carvedilol, or metoprolol succinate) that have been validated as effective by clinical trials should be prescribed. The effectiveness of these agents appears to be equal among men and women [14]. Clinicians should consider initiating carvedilol as a first-line therapy, given its broader antiadrenergic effects whenever possible. However, for patients with marginal blood pressure for whom partial α-blockade may be deleterious, metoprolol succinate or bisoprolol may be suitable first-line agents.

A β-blocker should be initiated for all β-blocker–tolerant ADHF patients for whom it has not been previously prescribed. In the intensive care unit setting, treatment should be initiated at very low doses and gradually uptitrated every few days or within 1 week. The usual starting doses are carvedilol 3.125 mg twice daily or metoprolol succinate 6.25 mg twice daily. Importantly, β-blockers should not be initiated until optimal volume status and hemodynamic stability have been achieved. The majority of ADHF patients will already be receiving β-blocker treatment. In general, β-blockers should not be withdrawn unless marked bradycardia or hemodynamic instability develops, owing to the risk of rebound hypertension and tachycardia. When necessary to achieve active diuresis for ADHF with hemodynamic instability, a 50% reduction in the
ambulatory dose is often preferable to drug cessation. In a retrospective observational study of over 2,300 patients eligible to receive β-blocker during hospitalization, Fonarow and colleagues demonstrated that continuation of β blocker was associated with a significantly lower risk of propensity-adjusted post-discharge death and rehospitalization rates compared to those who had β-blockers withdrawn [29].

Aldosterone Antagonists

Circulating aldosterone levels are elevated in relationship to heart failure severity, adversely affect prognosis, and contribute to deterioration of function and left ventricular remodeling following acute myocardial infarction. Potential deleterious effects include endothelial dysfunction, increased oxidative stress, enhanced platelet aggregation, activation of matrix metalloproteinases, and increased activation of the sympathetic nervous system. The mineralocorticoid receptor antagonist (MRA) spironolactone has been shown to reduce mortality of patients with severe heart failure by 30% [30]. Results of the EPHESUS trial confirm that eplerenone, a more selective MRA, can also reduce morbidity and mortality amongst patients with evidence of systolic dysfunction and heart failure following acute myocardial infarction [30]. The beneficial effects of MRA’s appear to be independent of their diuretic actions, and likely relate to interruption of the downstream adverse effects of aldosterone activation.

Spironolactone or eplerenone should generally not be initiated in the ICU setting. Both can be associated with serious hyperkalemia, particularly in the presence of impaired renal function or other medications which impair potassium excretion. An MRA (Table 194.5) should be added to the patient’s medical regimen prior to discharge following optimization of other heart failure therapies, provided that significant renal dysfunction (creatinine >2.5 mg per dL) or hyperkalemia (K+ >5.0 mEq per L) is not present. Patients who have been receiving these agents should continue taking them during hospitalization, unless marked hemodynamic instability, electrolyte disturbances, or worsening renal function are present.
INTENSIVE CARE MANAGEMENT OF ACUTE DECOMPENSATED HEART FAILURE

Congestive symptoms (pulmonary and/or systemic) are the most frequent reason for hospitalization in ADHF. Establishing the patient’s prior euvoletic weight and achieving it through diuretic dosing adjustments is critical for treating acute decompensation. Diuretics should be switched to intravenous administration whenever questionable oral absorption (i.e., postoperative state) is expected. Once daily ACE inhibitor or ARB therapy is ideal for outpatient management to enhance compliance; however, if hemodynamic instability is anticipated during hospitalization, a temporary switch to a short-acting agent (e.g., captopril in place of lisinopril) should be considered. Among patients with deteriorating renal function, it may be necessary to withhold the ACE-inhibitor or ARB and transiently substitute hydralazine and nitrates, particularly when serum creatinine exceeds 3.0 mg per dL. β-blocker dosing should remain unchanged and may require a modest increase if atrial tachyarrhythmias are encountered in the postoperative state (see below). Serum electrolytes should be followed frequently, given the potential for electrolyte imbalance (e.g., hypokalemia or hypomagnesemia) to potentiate atrial and ventricular arrhythmias among vulnerable patients.

Stevenson has popularized a 2-minute clinical assessment to ascertain the hemodynamic profiles for heart failure patients (Fig. 194.1) [31]. Patients are characterized in a 2 × 2 fashion according to the presence or absence of congestion and low or adequate perfusion on physical examination [31]. The clinical profiles thus defined have been shown to correlate reasonably well with direct hemodynamic measurements of filling pressure and cardiac output and are correlated with prognosis following hospital discharge [32]. “Warm and dry” patients have normal resting hemodynamics and are well compensated. For these patients, other potential etiologies for dyspnea or fatigue should be considered. The majority (70% to 80%) of patients admitted with worsening symptoms fit the “warm and wet” profile. These individuals are volume overloaded but have adequate end-organ perfusion. The primary treatment goal is thus relief of “congestive” symptoms using intravenous loop diuretics alone or in combination with a thiazide. Those who fail to respond to escalating doses of intravenous loop diuretics may benefit from a continuous intravenous loop diuretic infusion. A small minority of patients with refractory volume overload may benefit from continuous venovenous hemofiltration (CVVH) or ultrafiltration [14]. Although
neurohormonal antagonists including ACE-inhibitors, ARBs, and β-blockers should ideally be maintained during hospitalization, downward dose adjustment or temporary suspension (particularly of β-blockers) should be considered for patients who are difficult to diurese or who are hypotensive. A very small minority of patients (<5%) fall into the “cold and dry” profile. These individuals have impaired cardiac output but do not adequately utilize the Starling mechanism to increase preload. Judicious hydration should be attempted with assessment for obstructive cardiomyopathy by echocardiography. Patients who fail to demonstrate improvement of end-organ perfusion and impaired ventricular function may require a short-term infusion of a positive inotropic agent such as dobutamine or milrinone.

![Hemodynamic profiles of patients presenting with acute decompensated heart failure. Most patients can be classified in a 2-minute bedside assessment according to their physical signs and symptoms. This classification is useful in guiding therapy and predicting prognosis.](p.1881)

**FIGURE 194.1**

Echocardiography During ICU Management

Transthoracic echocardiography is an essential tool for the evaluation and management of the ADHF patient [33]. An echocardiogram should
be performed for all patients with a new diagnosis of heart failure to determine its etiology (i.e., systolic dysfunction, diastolic dysfunction, or unsuspected valvular disease). It is also useful for assessing right ventricular function, estimating pulmonary artery pressures and whether regional or global wall motion abnormalities are present. For patients with chronic heart failure, it can be useful for assessing potential causes for acute decompensation such as worsening left or right ventricular function, or the development of more severe valvular disease.

In addition to providing clinical essential information about cardiac structure and function, echo-Doppler can now provide estimates of right and left ventricular filling pressures and cardiac output measures that correlate well with catheter-based hemodynamics [33]. Central venous pressure can be estimated via measurement of the inferior vena caval diameter and respiratory variation; systolic pulmonary artery pressure is calculated as CVP + peak pressure gradient between the right atrium and right ventricle during systole. Left atrial pressure (LAP) is typically assessed using mitral valve inflow velocity; tissue Doppler of the septal and lateral mitral annulus; and pulmonary venous flow patterns. Echocardiography is most useful for differentiating high from low LAPs; however, there may be a considerable overlap in the intermediate range of pressures. These parameters can be measured serially to assess responses to therapy [33].

Hemodynamically Guided Therapy

Approximately 10% to 15% of patients with advanced heart failure will demonstrate marked hemodynamic deterioration on admission (“cold and wet” profile). These patients have impending cardiogenic shock [31,32]. Potential causes for acute decompensation such as recent myocardial infarction, rhythm change, worsening valvular disease, or medical/dietary noncompliance should be sought. The ESCAPE trial randomized patients with acute decompensation without hemodynamic compromise to conventional medical management based on physical findings and symptoms versus tailored hemodynamic monitoring following insertion of a pulmonary artery catheter. Somewhat surprisingly, outcomes did not differ between the two management strategies [34]. Certain high-risk subgroups may, nonetheless, benefit from short-term hemodynamic monitoring for management of ADHF. Principal indications for hemodynamic monitoring with a pulmonary artery catheter include evidence of worsening end-organ dysfunction, need for withholding vasoactive medications because of hypotension, heart failure associated with other comorbidities (i.e., unstable angina or valvular heart disease) or inability to wean positive inotropic support (Table 194.6). “Tailored” hemodynamic treatment for refractory heart
failure is outlined in Table 194.7 [32]. Following initial assessment of baseline hemodynamics, intravenous diuretics, vasodilators, or positive inotropes are administered to achieve desired hemodynamic goals which generally include a pulmonary capillary wedge pressure below 15 mm Hg and a cardiac index above 2.2 L/min/m². This intravenous program is maintained for 48 to 72 hours to affect desired diuresis and improve end-organ perfusion. Following this stage, oral vasodilators are uptitrated as intravenous agents are weaned. Further adjustment of diuretic dose and ambulation should be completed during the final 24 to 48 hours of hospitalization. This “tailored approach” produces sustained improvement of filling pressures, forward cardiac output, decreased mitral regurgitation, and decreased neurohormonal activation [32]. Oral vasodilator therapy and β-blockers should be withheld during treatment with intravenous vasoactive agents.

TABLE 194.6 Indications for Hemodynamic Monitoring in Decompensated Heart Failure

- Ongoing Congestive Symptoms and Suspected End-Organ Hypoperfusion
  - Narrow pulse pressure: Cool extremities
  - Declining renal function: Hypotension on ACE or ARB treatment
  - Mental confusion: Progressive hyponatremia
- Heart failure and other Medical Comorbidities
  - Cardiac: unstable angina pectoris; stenotic valvular lesions, and hypertrophic cardiomyopathy
  - Noncardiac: severe obstructive or restrictive pulmonary disease, advanced renal disease, and sepsis
- Other Situations
  - Perioperative monitoring to optimize status for a high-risk procedure
  - Symptoms disproportionate to clinical assessment of degree of compensation
  - Uncertain volume status
  - Inability to wean inotropic support

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.
Considerable controversy continues to exist regarding the relative roles of intravenous vasodilator drugs (i.e., nitroglycerin, nitroprusside, or nesiritide) versus positive inotropic agents (dobutamine, dopamine, or milrinone) in this population (Table 194.8). Previously, inotropic infusions have been used for patients with moderate heart failure in order to promote brisk diuresis. These agents, however, are associated with an increased risk of ischemic events and tachyarrhythmias [35]. A second major limitation of short-term inotropic support is the additional complexity needed to readjust oral regimens as the infusions are weaned [36]. Although positive inotropes should not be routinely used for “warm and wet” patients, these agents can be life saving for patients with progressive hemodynamic collapse [14,36]. Patients who present or develop obtundation, anuria, persistent hypotension, or lactic acidosis may only respond to inotropic support, which should be continued until the cause of cardiac deterioration is determined and definitive therapy implemented. A brief inotropic treatment may also be appropriate for patients who develop the cardiorenal syndrome [36]. It should be emphasized, however, that many patients with low cardiac output have high systemic vascular resistance that predictably improves with vasodilator therapy alone, obviating the need for inotropic support [37].

**TABLE 194.7 Principles of Hemodynamic Tailored Heart Failure Therapy**

| Measure baseline resting hemodynamics (CVP, PAP, PCW, CI, and SVR) |
| Administer intravenous diuretics, vasodilator (nitroprusside, nitroglycerin, or nesiritide) or inotropic agent (milrinone or dobutamine) dosed to achieve specific hemodynamic goals: |
| Pulmonary capillary wedge pressure <16 mm Hg |
| Right atrial pressure <8 mm Hg |
| Cardiac index >2.2 L/min/m² |
| Systemic vascular resistance <1,000–1,200 dynes-sec-cm⁻⁵ |
| Systolic blood pressure >80 mm Hg |
| Maintain optimal hemodynamics for 24–48 hours |
| Uptitration of oral vasodilators as intravenous vasodilators are weaned |
| Adjust oral diuretics to keep optimal volume status |

CVP, central venous pressure; PAP, pulmonary artery pressure; PCW, pulmonary capillary wedge pressure; CI, Cardiac index; SVR, systemic vascular resistance.

Adapted from Stevenson LW: Eur J Heart Failure 1:251–257, 1999 (Table 2, page 254); Used with permission.
In-hospital mortality has also been shown to be lower for nonhemodynamically compromised patients treated with intravenous vasodilators compared to positive inotropes [37]. Intravenous nitroprusside, a direct nitrosodilator, rapidly lowers filling pressures and improves cardiac output, which in turn, improves diuretic responsiveness. Hemodynamically monitored nitroprusside infusions rarely cause systematic hypotension but may be complicated by thiocyanate toxicity, particularly when high doses are required for prolonged periods of time for patients with preexisting hepatic or renal dysfunction. Intravenous nitroglycerin also produces arterial and venous dilatation but is less effective than nitroprusside. Nesiritide, a human recombinant form of endogenous BNP, rapidly improves symptoms. It has largely been utilized for patients demonstrating the “warm and wet” hemodynamic profile rather than those with more advanced “cool and wet” profiles. A small study suggested that short-term in-hospital nesiritide administration resulted in fewer heart failure rehospitalizations and lower 6-month mortality following discharge compared to dobutamine [38]. Further, perioperative nesiritide has been reported to improve renal function and enhance urine output following coronary bypass surgery [39]. However, the safety of nesiritide has been questioned, and the hope that this agent would attenuate renal dysfunction during heart failure treatment has not been realized. Neither the ASCEND-HF trial nor the DOSE-HF trial demonstrated any benefit of short-term nesiritide therapy for the treatment of ADHF [16,40]. Table 194.9 summarizes randomized clinical trials of ADHF therapies.

Biomarker-Guided Therapy

Serial BNP or NT-pro-BNP measurements to guide therapies for ambulatory patients are increasingly utilized. Small, controlled trials of chronic heart failure patients demonstrated fewer heart failure rehospitalizations using BNP levels to adjust pharmacologic therapy. However, this approach recently failed to improve survival free of repeat hospitalizations or quality of life in a large cohort of patients. A reasonable approach for inpatients with ADHF should include the
measurement of BNP or NT-pro-BNP on admission and prior to discharge when the patient is euvolemic, both for prognostic purposes as well as to aid in tailoring post-discharge treatment [41]. Daily biomarker measurement does not add significant prognostic value. A fall of 30% or greater in BNP or NT-pro-BNP at discharge identifies patients at low risk for readmission [42]. Conversely, a rise in either biomarker suggests worsening disease or inadequate therapy and should prompt a review of the patient’s heart failure regimen.
PERIOPERATIVE MANAGEMENT OF ADVANCED HEART FAILURE PATIENTS

Hernandez et al. have reported that patients with heart failure undergoing major noncardiac surgical procedures experience substantially increased morbidity and mortality compared to patients with ischemic heart disease or an age-matched population [43]. After adjusting for demographics, type of surgery, and co-morbidities, the risk-adjusted operative mortality (death before discharge or within 30 days of surgery) was 11.7% for heart failure patients, 6.6% for ischemic heart disease patients, and 6.2% for controls. Further, the risk-adjusted 30-day readmission rates were 20% for the heart failure cohort compared with 14% for the ischemic population and 11% for age-match controls. The presence of a third heart sound or signs of overt heart failure signs clearly identifies patients at increased risk for adverse outcome during noncardiac surgical procedures [43]. Every effort must be made to detect unsuspected heart failure by careful evaluation and to optimize therapy before embarking on nonemergent procedures.

Nonemergent surgical procedures should be delayed for ADHF patients. Volume overload should be corrected and adequate oxygenation insured. Maintenance pharmacologic therapy including vasodilators, β-blockers, and digitalis should be continued. A trough digoxin level should be checked and maintained < 1 ng per dL to minimize potential toxicity. Spironolactone should be withheld until stable hemodynamics and renal function have been achieved. Patients with refractory symptoms or deteriorating end-organ function should have a pulmonary catheter inserted in order to optimize their hemodynamics. Current evidence does not support the routine use of a pulmonary artery catheter for perioperative monitoring [44]. A single large scale randomized clinical trial of pulmonary artery catheterization in high-risk surgical patients demonstrated no improvement of survival [45]. However, only 16% of patients enrolled in this trial had symptomatic heart failure. Ejection fraction alone is insufficient to recommend the use of continuous hemodynamic monitoring. The majority of patients with markedly impaired ventricular function (LVEF < 20%) may be well compensated on optimized pharmacologic therapies and undergo surgery without invasive monitoring. Conversely, some patients with only moderate impairment of LVEF may benefit from pulmonary artery monitoring when hemodynamic instability is anticipated. Practice guidelines for intraoperative hemodynamic monitoring published by the American Society of Anesthesiologists consider the severity of the patient’s
underlying cardiovascular disease, the type of surgical procedure, and the likelihood of major hemodynamic lability [46]. The extent of anticipated intraoperative and perioperative fluid shifts is another key factor. Current ACC/AHA guidelines recommend intraoperative pulmonary artery monitoring as a Class 2B indication, as indicated for patients at risk for major hemodynamic disturbances that are easily detected by pulmonary artery catheter who are scheduled to undergo a procedure that is likely to cause these hemodynamic changes [44].
MECHANICAL CIRCULATORY SUPPORT

A small minority (1% to 2%) of patients admitted with ADHF will progress to cardiogenic shock that fails to respond to inotropic or vasodilator support. If a potentially reversible cause is identified (e.g., acute myocarditis) or if the patient qualifies to be a candidate for heart transplantation, short-term mechanical circulatory support should be considered [47]. An intra-aortic balloon pump can increase cardiac output and improve diastolic coronary artery filling. However, it has not been shown to improve survival when shock complicates acute myocardial infarction and its role for refractory ADHF has not been established [48]. Newer percutaneous support devices (i.e., Tandem Heart, Impella 5.0) provide greater hemodynamic benefits than IABP but have not yet been demonstrated to improve outcomes [47,49]. Extracorporeal membrane oxygenation (ECMO) may be lifesaving for patients with advanced biventricular dysfunction or those with shock and inadequate oxygenation. Short-term support is well tolerated with the newer devices, but in-hospital mortality remains high [49].
Atrial and ventricular arrhythmias are nearly ubiquitous among advanced heart failure patients and often contribute to clinical decompensation. Atrial fibrillation and flutter are the most commonly encountered supraventricular arrhythmias. The likelihood of atrial fibrillation increases with heart failure severity and approaches 40% for NYHA class III and IV patients [50]. The potential adverse effects of atrial fibrillation include loss of atrioventricular synchrony, rapid or inappropriately slow ventricular response rates, variable diastolic filling times, and thromboembolic complications. Patients with a known history of chronic atrial fibrillation should have adequate heart rate control and anticoagulation whenever feasible (see below). Uncontrolled, sustained, rapid (>120 beats per minute) atrial fibrillation can result in a reversible dilated cardiomyopathy or, more typically, can worsen preexisting left ventricular systolic dysfunction [50]. A heart rate below 100 beats per minute during modest ambulation is a reasonable goal. β-adrenergic blockers remain the most effective rate-control treatment option [51]. Addition of digoxin may be considered when necessary for adequate rate control. A large recent registry analysis found no increase of mortality risk by treating new-onset atrial fibrillation of heart failure patients [50]. Calcium channel blockers (e.g., diltiazem and verapamil) should generally be avoided during ADHF owing to their negative inotropic effects. Amiodarone is a highly effective drug for rate control, and is frequently useful for controlling persistent atrial arrhythmias for ICU patients [51].

Atrial fibrillation commonly occurs during hospitalization owing to enhanced sympathetic stimulation. For all patients, thyroid function should be assessed to exclude hyperthyroidism as a contributing factor. For ADHF patients who are hemodynamically stable, initial therapy should focus on adequate rate control (HR < 100 per minute). For patients who experience active angina pectoris or hemodynamic instability during rapid atrial fibrillation, urgent synchronized cardioversion should be performed followed by initiation of an atrial stabilizing agent to prevent recurrence. For ADHF, restoration or maintenance of sinus rhythm is often desirable; amiodarone or dofetilide remain the most useful antiarrhythmic drugs [50,51]. Amiodarone is particularly well tolerated from a hemodynamic standpoint; the loading dose of amiodarone should be kept below 1,000 mg per day to prevent further exacerbation of heart failure symptoms. Dronedarone, a non-iodinated derivative of amiodarone, has also been shown to be effective for maintenance of sinus rhythm and rate control for rapid atrial
fibrillation. However, increased mortality due to worsening heart failure has been reported among patients with depressed LV function; this agent should not be utilized for heart failure patients [52].

Dofetilide is a class III anti-arrhythmic drug that blocks the repolarizing potassium current. It is highly effective for restoring sinus rhythm but has been associated with torsades de pointes in up to 3% of patients [51]. Continuous ECG monitoring for the first 48 hours after initiation in the hospitalized patient is essential. Sotalol, an additional class III antiarrhythmic drug, may occasionally be substituted for other β-blockers, following improvement in ADHF, but it carries with it a similar risk of torsades, and is generally less effective than amiodarone.

Asymptomatic nonsustained ventricular tachycardia (NSVT) occurs among over 50% of patients with NYHA class III/IV heart failure [53]. Pharmacologic suppression of NSVT does not lower the risk of sudden death. Asymptomatic ventricular ectopy should be viewed as a marker of disease severity rather than a specific marker for sudden cardiac death risk [53]. Heart failure patients often develop frequent ventricular premature beats or short runs of NSVT during their ICU stay. Precipitating causes such as electrolyte disturbances (e.g., hypokalemia or hypomagnesemia), enhanced sympathetic tone, a decrease of β-blocker dose, or withholding of prior anti-arrhythmic therapy should be considered. The majority of patients have no symptoms and do not require pharmacologic suppression. Frequent runs of ventricular tachycardia or sustained monomorphic VT require anti-arrhythmic treatment. Amiodarone (intravenous 0.50 to 1.0 mg per minute) or lidocaine (0.5 to 2 mg per minute) are generally most effective for acute management [54]. β-blockers, sotalol, and amiodarone are effective long-term oral treatment options [54].

A growing percentage of advanced heart failure patients have implantable cardioverter defibrillators (ICDs) to treat symptomatic ventricular tachyarrhythmias or for primary prevention of sudden cardiac death. The ICD should be interrogated for any recent atrial or ventricular arrhythmias prior to admission, and the device temporarily inactivated prior to surgical procedures that involve electrocautery. It should be reactivated and its function checked by an electrophysiologist in the early perioperative period.

**Anticoagulation**

Systemic anticoagulation is often a part of a heart failure patient’s
outpatient management. Studies have suggested that the risk of thromboembolic complications is lower than previously expected, averaging 1.5 to 3 episodes/100 patient years when normal sinus rhythm is present. Current indications for systemic anticoagulation include paroxysmal or chronic atrial fibrillation, a history of thromboembolism, or echocardiographically documented left ventricular thrombus [55,56]. Relative indications include a markedly dilated left ventricle (>75 mm) with severe systolic dysfunction and spontaneous echocardiographic contrast (“smoke”), indicating sluggish intracavitary blood flow. The presence of a low ejection fraction alone is insufficient to warrant systemic anticoagulation. A non–vitamin K antagonist agent or Warfarin should be continued with an INR goal of 2.0 to 3.0 when invasive procedures are not planned. If surgery or central venous catheter placement are required, warfarin can be reversed with vitamin K or fresh frozen plasma, agent specific reversal of selected non–vitamin K antagonist can be accomplished, and transiently substituted with intravenous heparin or subcutaneous low-molecular weight heparin as feasible. For those patients who require anticoagulation but are unable to receive heparin (e.g., owing to heparin–induced thrombocytopenia), alternative anticoagulants including the direct thrombin inhibitors argatroban and hirudin, or the pentasaccharide fondaparinux can be considered. Non–vitamin K antagonist anticoagulants (i.e., dabigatran, rivaroxaban, and apixaban) are increasingly replacing warfarin for outpatient management of nonvalvular atrial fibrillation [57]. These agents should be continued unless invasive procedures are anticipated.
CONCLUSIONS

The patient with advanced heart failure or ADHF requires special considerations. Meticulous attention to volume status and maintenance of appropriate vasodilator therapy and β-adrenergic blockade form the cornerstones of acute management. Negative inotropic drugs and agents that might further impair renal function should be avoided. Patients with refractory symptoms or recent decompensation may require hemodynamic monitoring via a pulmonary artery catheter, and initiation of short-term vasoactive therapy including nitroprusside, nitroglycerin, milrinone, or dobutamine. Maintenance of sinus rhythm should be considered, and pharmacological suppression of recurrent ventricular tachyarrhythmias is often necessary. With careful management, hospital morbidity and mortality can be minimized despite the presence of advanced symptomatic heart failure.

Chapter 195

Management of the Cardiac Arrest Survivor

MICHAEL G. SILVERMAN • BENJAMIN M. SCIRICA

More than 500,000 people suffer a cardiac arrest (CA) each year in the USA. Out-of-hospital (OH) CA affects almost 350,000 people annually, and only 10% to 12% survive to hospital discharge [1]. Although survival has improved over the last several years, the mortality associated with CA remains extremely high [2]. Among those with an OHCA who survive to hospital presentation, the mortality rate is almost 60%. For the nearly 210,000 people who suffer an in-hospital (IH) CA each year, the mortality rate approaches 75% [1].

Although there are multiple causes of CA, hypoxemia–ischemia–reperfusion that arises during a CA and resuscitation can lead to a common pathophysiology that often results in multisystem organ dysfunction and neurologic injury, irrespective of the precipitating event [3]. In this chapter, we discuss the general approach to managing patients post-return of spontaneous circulation (ROSC) following a CA.

THE ROLE OF CORONARY ANGIOGRAPHY

Acute coronary syndrome (ACS) is a common cause of CA, and guidelines recommend performing a 12-lead electrocardiogram (ECG) as soon as possible following ROSC [3]. An observational analysis of post-CA patients taken for coronary angiography demonstrated that almost all patients (96%) with ST elevation on ECG had a significant coronary artery lesion [4]. Several observational studies have reported improved outcomes associated with coronary angiography among patients with ST elevation following OHCA [5–19]. In fact, the current guidelines recommend emergent coronary angiography for patients with OHCA with
ST elevation on ECG (Class I recommendation) [3].

For patients without ST elevation on ECG, the role of emergent coronary angiography is less clear. An analysis from the PROCAT registry demonstrated that among individuals without ST segment elevation following OHCA, percutaneous intervention (PCI) was associated with improved outcomes [20]. It is important to recognize, however, that there are no randomized controlled trials evaluating the role of coronary angiography and PCI for comatose individuals following OHCA. The current guidelines provide a class IIa recommendation that the decision to proceed with coronary angiography should be made regardless of neurologic status and that coronary angiography is reasonable for comatose individuals following OHCA of suspected cardiac etiology but without ST-segment elevation in the setting of hemodynamic or electrical instability [3].
HEMODYNAMIC TARGETS

Hypotension is common following CA and is associated with worse outcomes [21,22]; however, there is limited randomized clinical trial data to support specific targets and the observational data is mixed. The current guidelines consider it reasonable (class IIb) to avoid and treat hypotension (systolic blood pressure [SBP] less than 90 mm Hg or mean arterial pressure [MAP] less than 65 mm Hg), but do not provide specific blood pressure targets. Similarly, owing to a lack of data, the guidelines do not provide definitive recommendations regarding other hemodynamic measures.

Observational studies have targeted MAP goals of greater than 65 mm Hg up to greater than 90 mm Hg [23–25], with no difference seen in cerebral tissue oxygenation among individuals with a MAP of 70 mm Hg compared to a MAP of 90 mm Hg [25]. Therefore, a MAP goal of 70 to 75 may be reasonable [26]. Given the potential vasodilation from the post-CA inflammatory state, targeting a central venous pressure greater than 10 to 12 mm Hg is reasonable to help prevent hypotension and decrease vasopressor requirements [27].
TARGETED TEMPERATURE MANAGEMENT

Among individuals with ROSC following CA, neurologic mortality and morbidity is substantial. Roughly 80% of patients with ROSC remain comatose [28] and many of the deaths are attributed to neurologic injury [29]. Targeted temperature management (TTM) for comatose individuals post-CA has the potential to improve survival and neurologic outcomes. Figure 195.1 demonstrates the phases of targeted temperature management.

![Phases of Targeted Temperature Management](image)

**Figure 195.1** Phases of targeted temperature management.

**Indications for TTM**

Two randomized clinical trials published in 2002 led to the initial adoption of therapeutic hypothermia (TH) following OHCA [30,31]. Both studies included comatose patients with ROSC following a ventricular fibrillation (VF) OHCA. Patients were randomized to either cooling to a temperature between 32°C and 34°C over 12 to 24 hours, or no temperature management at all. Both trials demonstrated significantly improved outcomes, with very low numbers needed to treat (roughly 6) for both improved survival and neurologic outcomes [32].

The TTM trial [33], the largest randomized clinical trial of temperature management following OHCA, randomized all individuals to 1 of 2 actively managed temperatures: 33°C versus 36°C for 28 hours, at which
time gradual rewarming (0.5°C per hour) was initiated. At 6 month follow-up, there was no difference in mortality (50% for the 33°C group versus 48% for the 36°C group, \( p = 0.51 \)) or in rates of poor neurologic outcome (52% for each group, \( p = 0.87 \)). Importantly, nearly 20% of individuals in the TTM trial had an initial nonshockable rhythm. The similar outcomes between treatment strategies were observed for all important subgroups of patients (e.g., shockable versus nonshockable rhythms; time to return of normal circulation; and age).

The current American Heart Association and International Consensus on Cardiopulmonary Resuscitation guidelines now provide strong recommendations for the use of TTM for all comatose patients with ROSC following CA (Table 195.1). This includes OHCA with shockable and nonshockable rhythms, as well as all individuals with an in-hospital CA (IHCA) regardless of rhythm [3,34]. It is worth noting that the American Heart Association increased the strength of the recommendation for TTM for patients with nonshockable rhythms from class IIb to I, despite the absence of any appropriately powered randomized studies in this population.

ROSC, return of spontaneous circulation; VF, ventricular fibrillation; pVT, pulse-less ventricular tachycardia; OHCA, out-of-hospital cardiac arrest; IHCA, in-hospital cardiac arrest; TTM, targeted temperature management.
Initiation of TTM

The optimal timing for TTM initiation and time to target temperature remain uncertain; however, observational patient data and animal data suggest worse outcomes with delayed initiation of TTM. Given these findings, there has been interest in the potential for prehospital initiation of TTM. However, Kim et al. demonstrated that prehospital cooling with cold saline did not lead to better survival or neurologic outcomes, and in fact was associated with higher rates of pulmonary edema and rearrest [35]. The detrimental effects of iced saline infusions were confirmed by the RINSE Trial, which found that early infusion of up to 2 L of iced saline was associated with a lower rate of successful ROSC [36]. As a result, the current guidelines recommend against the routine initiation of prehospital cooling with cold fluids. Therefore, it seems reasonable to initiate TTM as soon as possible on hospital arrival for comatose patients with ROSC following OHCA using ice packs, standard cooling blankets, or intravenous or surface cooling devices. The need for invasive coronary angiography should not delay initiation of TTM, because the use of TTM during invasive coronary angiography and PCI is both safe and feasible [4,17,37].

Target Temperature

The initial TH trials from 2002 targeted a goal temperature of 32°C to 34°C and 33°C [30,31]. A subsequent smaller pilot study demonstrated improved outcomes associated with 32°C versus 34°C [38], suggesting that lower temperatures might be better. In contrast, the more recent and larger TTM trial demonstrated similar outcomes between individuals randomized to 33°C versus 36°C [33]. Although there was no difference in outcomes between these two treatment groups, it is crucial to remember that this was a trial of two active temperature management interventions (33°C versus 36°C). The current guidelines recommend for a target temperature of 32°C to 36°C for at least 24 hours. The temperature range in the guideline recognizes uncertainty regarding the hypothesis that some individuals may benefit from greater degrees of hypothermia, whereas others may be at an increased risk of complications at lower temperatures (such as bradycardia), and thus can be effectively treated at a more moderate target temperature.

Methods of Cooling

Several methods for cooling have been used in the setting of TTM.
Traditional methods have included cold intravenous fluid and ice packs. Alternative methods have included surface cooling methods such as blankets and gel pads with circulating cold water. Intravascular methods also exist that function via heat exchange [39]. An intranasal approach has also been used in the intra-arrest setting [40]. Although there is data demonstrating different rates of achieving and maintaining target temperature, no particular method has been associated with better outcomes than the others. As mentioned above, intravenous iced saline should not be used to initiate TTM.

Routine Care During Targeted Temperature Management

Sedation, Analgesia, and Shivering

Sedation and analgesia are an integral part of TTM until the patient has returned to normothermia [26]. All patients undergoing TTM should receive appropriate sedation and analgesia, typically a low dose, continuous infusion. Between 35°C and 37°C, shivering occurs frequently as a physiologic reaction. Shivering slows the time to target temperature and increases metabolic activity, so it should be treated aggressively. Blankets and a hot air warmer are nonpharmacologic methods to prevent and treat shivering. A bolus of intravenous magnesium can also help raise the shivering threshold. Increasing analgesia and sedation can also reduce shivering. If, however, shivering persists after these measures, then neuromuscular blockade can be effective. There are varying approaches to the use of neuromuscular blockade (selective versus continuous), which are currently being evaluated in ongoing clinical trials. If a patient is not cooling at a rate of 1°C per hour, then an empiric bolus of a neuromuscular blockade may help reduce subclinical shivering and achieve the target temperature more quickly.

Seizure Surveillance

The evaluation and management of seizures is another key component of neurologic care post-CA, because up to 12% to 22% of patients following CA will have seizure activity [3]. Nonconvulsive status epilepticus is a potential reason for patients not to regain consciousness and can be associated with secondary brain injury. In addition to potentially further injuring the brain, seizure activity also carries a poor prognosis. Therefore, it is important to recognize and manage nonconvulsive status epilepticus appropriately. Frequent or continuous EEGs are recommended for all comatose patients with ROSC following CA.
Ventilation and Oxygenation

Management of mechanical ventilation is an important component of post-arrest care. Ventilation should be targeted to maintain a PaCO\textsubscript{2} in the normal range (35 to 45 mm Hg). Hypocapnia has been associated with decreased cerebral perfusion \cite{25} and worse outcomes in observational studies \cite{41,42}. Similarly, oxygenation should be targeted within a range to avoid episodes of hypoxia (PaO\textsubscript{2} less than 60 mm Hg) as well as hyperoxia (PaO\textsubscript{2} greater than 300 mm Hg), with current recommendations to titrate FiO\textsubscript{2} to maintain oxygen saturation greater than 94\% \cite{3}.

Hyperglycemia

Hypothermia decreases pancreatic insulin secretion and increases insulin resistance, leading to hyperglycemia \cite{26}. Blood glucose should be monitored hourly. The optimal glucose target remains debated. No difference in 30-day survival was seen in one randomized clinical trial comparing tight control (72 to 108 mg per dL) versus moderate control (108 to 144 mg per dL) in the post-CA setting. There is currently no data to support that glycemic control for post-CA patients should differ from any other critical care setting \cite{3}, though avoidance of hypoglycemia is key because it could exacerbate neurologic damage.

Potassium

Hypokalemia is also a common occurrence during the cooling process because of both the inward cellular shift of potassium, and the modest diuresis and kaliuresis in the setting of hypothermia. Electrolytes should therefore be monitored frequently (every 4 to 6 hours) and repleted appropriately. Potassium repletion should then be held starting 4 hours prior to the rewarming phase because of the reversal of cellular shift as potassium returns to the serum.

Infection

Infection can occur frequently among post-CA patients undergoing TTM. This can be from a combination of exposure from possible aspiration, emergent intubation, mechanical ventilation, and possible catheter related infections in the setting of potential immune suppression from TTM.
Electrocardiography

The most common arrhythmia of TTM is sinus bradycardia. At cooler temperatures, the PR interval will prolong and patients can experience a junctional escape rhythm. Rewarming by 1°C to 2°C will resolve conduction abnormalities. Cooling can also prolong the QT interval, again in a “dose-dependent” fashion, though there is no evidence to suggest it precipitates torsade-de-pointes. Osborn, or J waves, may be present in up to 20% of patients, depending on the target temperature [43]. No specific therapy is required for any non–life-threatening arrhythmia, but rewarming by 1°C to 2°C will resolve most conduction abnormalities.

Hemodynamics

A substudy from the Targeted Temperature Management trial [44] demonstrated the effect of hypothermia on hemodynamics (Fig. 195.2). A target temperature of 33°C was associated with an increase of systemic and pulmonary vascular resistance when compared with a target temperature of 36°C. Although the lower temperature was associated with decreased cardiac index, this was thought to be largely mediated by a reduction in heart rate, and there was no difference in left ventricular ejection fraction between the groups.

![FIGURE 195.2 Hemodynamic effects of targeted temperature management. A: The change in temperature. B: The change in cardiac index. C: The](#)
Return to Normothermia

Gradual rewarming (0.25°C to 0.5°C per hour) should be initiated at least 24 hours after TTM initiation [3]. Rewarming faster than this raises the risk of hypoglycemia, hyperkalemia, and hypotension (from vasodilation). Once the TTM protocol has been completed and the patient has achieved normothermia, actively avoiding fever among patients who remain comatose is reasonable, because hyperthermia has been associated with worse neurologic outcomes in other critical care settings [45,46]. This can often be achieved by leaving the temperature management system in place [3] and by the use of antipyretics.
NEUROLOGIC PROGNOSTICATION

Providing a neurologic prognosis following CA is a complicated task that often requires multimodality tools including physical examination, EEG, neuroimaging, somatosensory evoked potentials (SSEPs), and serologic biomarkers. Despite advances in post-resuscitation care, neuroprognostication remains the most challenging aspect of care, because no test has acceptable levels of certainty. Few patients meet formal criteria for brain death after resuscitation and most patients have intact brainstem function, such that the patient has spontaneous ventilation. Ideally, a test would identify patients at an early stage with the potential for a good neurologic outcome while also indicating which patients have no chance of meaningful neurologic recovery.

Timing

The ideal timing for neurologic prognostication for comatose patients following CA remains uncertain. The ultimate goal is to identify a time point that minimizes (or eliminates) the risk of inaccurately predicting a poor neurologic outcome, thus avoiding a “false positive.” For patients who have not been treated with TTM, a minimum of 72 hours following ROSC is suggested [3,47]. Patients undergoing TTM experience delayed neurologic recovery; therefore it is important to wait a minimum of 72 hours post-return to normothermia when the patient is off of all potentially sedating medications and free of other confounding illnesses, before assessing for neurologic prognosis [3,48].

There are few clinical criteria that clearly identify patients with a poor neurologic prognosis. The TTM trial specified the clinical scenarios listed in Table 195.2 as acceptable criteria for poor prognosis that would justify the transition to comfort care. Many patients will not fulfil these criteria, thus leaving the clinician to use the diagnostic tests discussed below to help guide therapy and prognosis.

• Minimum 72 hours after intervention period: Glasgow motor score 1–2 and treatment refractory status epilepticus

aThis finding was permitted for poor neurologic prognostication prior to 72 hours after targeted temperature management.

Diagnostic Testing

The absence of pupillary light reflexes at 72 hours following CA is considered a reasonable predictor of poor neurologic outcome for TTM and non–TTM-treated patients [3]. The absence of motor movements, extensor posturing, and myoclonus have fairly high false-positive rates (up to nearly 10%), and therefore should not be used to predict poor neurologic outcome [3].

A lack of EEG reactivity at 72 hours post-CA, and persistent burst suppression after rewarming are considered reasonable predictors of poor neurologic outcomes for TTM-treated patients [49]. Status epilepticus for more than 72 hours is also a reasonable marker of poor neurologic outcome. In non–TTM-treated patients, burst suppression at 72 hours post-CA is a reasonable marker of poor neurologic prognosis when combined with other predictors [3]. Research into earlier EEG patterns post-arrest is ongoing to identify both good and poor prognostic patterns.

SSEPs test the cortical response to peripheral median nerve stimulation. Independent of whether patients undergo TTM, an SSEP 24 to 72 hours post-CA demonstrating the bilateral absence of the N20 waveform is a reasonable predictor of poor neurologic outcome [3].

Computed tomography (CT) or magnetic resonance imaging (MRI) of the brain to evaluate for edema can provide useful measures in support of poor neurologic outcome. Imaging immediately post-arrest it is less likely to help with prognosis, unless there is evidence of hemorrhage, trauma, or herniation. Many patients without long-term neurologic recovery will have normal CT imaging within the first 24 hours. The optimal timing for MRI is after re-warming.

Neuron-specific enolase (NSE) and S-100B, two of the more commonly evaluated serologic tests for predicting poor neurologic outcomes, have
been shown to have high false-positive rates. As a result, they are not recommended for use in isolation and should only be used as supportive information in combination with other tests and clinical findings [3].

In general, a combination of certain diagnostic testing can help to increase the specificity for a poor neurologic prognosis [50]. Rarely will one test be the deciding factor in prognosis; rather, the integration of all testing, combined with the patient’s age and co morbidities, will allow a multidisciplinary team to provide the most appropriate prognosis for patients.
Caring for post-CA patients involves a multifaceted and multisystem approach to evaluate and treat the underlying cause of arrest and to minimize and prevent further progression of end organ damage (Table 195.3). For patients who remain comatose following ROSC, TTM can improve survival and neurologic outcomes, and is now recommended as standard of care regardless of the presenting rhythm. Despite the advances of post-arrest care that have led to improved outcomes (Table 195.4), many questions regarding the routine care and prognostication of these patients remain. Care for the post-CA patients requires a multidisciplinary team of intensivists, cardiologists, neurologists, social workers, and nurses. Only through team-based care at centers with resources and experience can the most contemporary treatments be delivered.

### TABLE 195.3 Principles of Management for the Post-Cardiac Arrest Patient

- Identify and treat the underlying cause of cardiac arrest
- **Acute Cardiovascular Care**
  - Obtain EKG
  - STEMI → Coronary Angiography
  - NSTEMI with hemodynamic or electrical instability → coronary angiography
- **Hemodynamics**
  - Avoid and treat hypotension (SBP < 90 mm Hg, MAP < 65 mm Hg)
  - Consider goal MAP ~70–75
- **Mechanical Ventilation**
  - Maintain normocarbia: PaCO₂ 35–45 mm Hg
  - Maintain oxygen saturation > 94%
- **Targeted Temperature Management (TTM) for comatose patients (regardless of rhythm)**
  - Initiate TTM as soon as possible on hospital arrival
    - TTM can be started prior to and continued during coronary angiography
- Target temperature: 32°C–36°C
- Initiate gradual rewarming ≥ 24 h after starting TTM protocol
- Check blood glucose every hour
- Check electrolytes every 4–6 h
- Neurologic monitoring for comatose patients
  - Continuous EEG as soon as possible following cardiac arrest
  - Consider somatosensory evoked potentials (SSEPs) 24–72 h post-arrest
- Neurologic prognostication should be delayed until:
  - at least 72 h post-return to normothermia for patients treated with TTM
  - at least 72 h post-arrest for patients not treated with TTM

INTRODUCTION

Cardiac device technology has made great advancements since the introduction of the first implantable pacemaker in 1958. Since then, the number of cardiac device implants continues to increase annually. The driver of this increase includes a larger burden of cardiac dysfunction related to the aging of the general population, expanding indications for device therapy, and ongoing innovation of the technology for cardiac pacing and defibrillation. As a result, many patients presenting to the intensive care unit (ICU) with noncardiac illnesses may have implanted cardiac devices. This chapter aims to briefly review basic cardiac device function and programming with emphasis on device malfunction and troubleshooting. A discussion of the indications for permanent pacing, defibrillator, or resynchronization therapy is beyond the scope of this text; for additional information regarding these topics, the reader is referred to the American College of Cardiology/American Heart Association/Heart Rhythm Society 2012 Focused Update of the 2008 Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities [1].
GENERAL DEVICE MANAGEMENT

Normal Device Function and Special Considerations

Identification of the type of device is critical for interpretation of its function. Although patients would ideally be able to provide information regarding the type of device that has been implanted (pacemaker, implantable cardioverter defibrillator [ICD], cardiac resynchronization device, among others) or carry a device identification card with them at all times, this is frequently not the case for hospitalized patients. Substantial device information can be gleaned from a chest radiograph, including the lead configuration, the type of device, abnormalities of lead position or integrity, and even the device manufacturer (Fig. 196.1A to E). Identification of the device manufacturer is essential when formal device interrogation or reprogramming is planned as each device company uses different software and programs to communicate with their respective devices (Fig. 196.2). The overwhelming majority of devices implanted are manufactured by 1 of 3 companies, and patient device information and technical support are available 24 hours a day (Table 196.1).
FIGURE 196.1 Information regarding implantable cardiac devices can be gained from chest radiograph. A: Dual chamber pacemaker with leads in the RA and RV. B: Single chamber, dual coil defibrillator with high voltage conductors in the RV and SVC–RA junction. C:
Cardiac resynchronization device with leads in the RA, RV, and CS. These devices may or may not have defibrillator function. D: Subcutaneous implantable cardioverter defibrillator (S-ICD) with generator in the left anterior-to-mid axillary line and defibrillator lead tunneled subcutaneously to the left parasternal region with the coil between the xyphoid process and suprasternal notch. E: Leadless pacemaker implanted in the RV. RA, right atrium; RV, right ventricle; SVC, superior vena cava; CS, coronary sinus; CAN, generator; SQ LEAD, subcutaneous lead.

</table>
Conventional device systems consist of a pulse generator or battery, logic circuits, pacing lead(s), and/or defibrillator lead(s). Cardiac implantable electronic device (CIED) therapy is rapidly evolving with novel technologies aimed at limiting vascular access or avoiding the vasculature entirely. The first subcutaneous ICD (S-ICD) was approved for use in the United States by the Food and Drug Administration in 2012 while, to date, no leadless pacemakers are approved by the FDA although postmarket studies are currently enrolling subjects. All implantable cardiac devices have programmable pacemaker functions with the exception of the current S-ICD device. Although the S-ICD can deliver transient backup pacing following defibrillator therapy, pacing is delivered transcutaneously and is not currently a viable long-term pacing option. Apart from the S-ICD, CIED both sense intrinsic electrical depolarization and excite myocardial tissue through an artificial electrical stimulus delivered near the lead/device tip. Electrical stimuli can be delivered in many ways depending upon how the device is programmed. Pacing nomenclature is standardized to easily communicate information regarding the device and the pacing mode (Table 196.2). Pacing algorithms are best understood as a function of timing cycles. A pacemaker operates like a timer with programmable intervals to coordinate all sensed and paced events. Nontracking modes of pacing (AAI, VVI, and DDI) deliver electrical impulses at set intervals (lower rate limit) unless a sensed electrophysiologic cardiac event occurs in the appropriate chamber before the end of the programmed interval (in which case the timer resets, Fig. 196.3). Dual chamber devices programmed to a tracking mode can provide pacing at the programmed lower rate or track sensed intrinsic conduction up to a programmed upper rate limit. There is no sensing in asynchronous pacing modes (AOO, VOO, and DOO) and electrical stimuli are produced at programmed intervals unaffected by intrinsic conduction.

FIGURE 196.3 Timing of events in various pacing modes. AAI is an atrial nontracking mode of pacing that provides backup atrial pacing at the programmed lower rate limit. Similarly, VVI is a ventricular nontracking mode of pacing that provides backup ventricular pacing at the programmed lower rate limit. DDD is a dual chamber mode of pacing that can both inhibit and trigger events in both the atrium and the ventricle. AS, atrial sensed event; AP, atrial paced event; VS, ventricular sensed event; VP, ventricular paced event; LR, lower rate limit.

Magnets
The placement of a magnet over a device affects pacemakers and
defibrillators differently. Application of a magnet to a pacemaker will cause the reed switch to close and result in asynchronous pacing. The pacing rate is company-specific with a different rate once battery depletion has occurred. Thus, placement of a magnet over the device can assist with the determination of battery status and device identification. If exposure to electromagnetic interference (EMI) is anticipated, positioning a magnet over the device can prevent inappropriate pacing inhibition. Upon removal of the magnet, the pacing mode will revert to the originally programmed settings, and, in general, formal device interrogation is not required. In contrast, application of a magnet to a defibrillator will disable all antitachycardia therapies but will not affect the pacing mode. Therefore, magnets can be used to prevent inappropriate therapies due to supraventricular tachycardia (SVT), lead fracture, or EMI. Upon removal of the magnet, defibrillator therapies will be restored, and, in general, formal device interrogation is not required.

**Electromagnetic Interference**

CIEDs are susceptible to strong electromagnetic fields [2]. In the hospital, many potential sources of EMI exist. Sources of electromagnetic energy that could possibly interfere with device function include magnetic resonance imaging (MRI), electrocautery, defibrillation, radiation therapy, neurostimulators, TENS units, radiofrequency ablation, electroconvulsive therapy, video capsule endoscopy, extracorporeal shock-wave lithotripsy, and therapeutic diathermy [3,4]. EMI exposure most commonly results in inappropriate inhibition or triggering of pacing stimuli, inappropriate ICD tachyarrhythmia detection and therapy and reversion to an asynchronous pacing mode (*noise-reversion mode*).

Inappropriate inhibition of ventricular pacing can be catastrophic for the pacemaker-dependent patient; similarly atrial oversensing with inappropriate ventricular tracking could result in a myriad of symptoms and induce heart failure, hypotension, or angina. Improper ICD tachyarrhythmia detection due to EMI could potentially be arrhythmia-inducing as a result of unsynchronized inappropriate shock delivery during the vulnerable period of repolarization. Noise-reversion mode is an algorithm that reverts transiently to asynchronous pacing in response to rapid frequency signals. The algorithm is designed to protect against inappropriate inhibition of pacing when high frequency signals are sensed. Although this algorithm is present in all pacemakers regardless of manufacturer, this is not the case for ICDs. Less frequently, EMI can result in reprogramming of the device parameters or permanently damage circuitry or a lead. When EMI exposure is unavoidable, certain measures can be taken to minimize the potential risks. For example,
pacemaker or defibrillator patients requiring surgery with electrocautery should have a magnet placed over the device during the operation. Other forms of EMI (e.g. MRI, radiation therapy, among others) carry substantial risk and may prompt the revision or removal of the entire cardiac device system prior to the magnetic exposure. Care should be taken to avoid sources of EMI for device patients or, if exposure to EMI cannot be avoided, at a minimum, measures should be taken to minimize potential harm with consideration of device interrogation following exposure.

**Mode Switch**

Mode switch is a programmable pacing algorithm that automatically changes the pacing mode to a nontracking mode in response to a sensed atrial arrhythmia. The purpose of this algorithm is to prevent inappropriately fast ventricular tracking at the upper rate limit in response to a rapid atrial tachyarrhythmia. Once the device has mode switched, it will remain in a nontracking mode until the atrial rate has fallen below the mode switch threshold for a specific number of intervals. This algorithm is very useful for patients with paroxysmal atrial arrhythmias (e.g. SVT, atrial fibrillation, or atrial flutter). The atrial rate at which mode switch occurs is programmable in most devices and the feature can even be programmed “off.”

**Line Management**

The placement of central venous catheters in cardiac device patients warrants special consideration. Depending upon the location and age of the device and the planned location of central venous access, a number of potential complications can occur. Reported complications associated with central venous catheters in cardiac device patients include lead damage from needle puncture [5], lead dislodgement and inappropriate ICD therapies [6]. Additionally, central venous stenosis as a consequence of prior cardiac device implantation may present a challenge to central venous catheter placement ipsilateral to the device [7]. Cardiac device infections and device-related endocarditis represent a particularly serious hazard of indwelling central venous catheters necessitating removal of the entire device system [8]. Central venous access should be performed contralateral to the device whenever possible.

**MRI**

The likelihood that patients with cardiac devices will require an MRI is high but this imaging modality is not without potential risks for these
patients. To minimize these risks, MRI-conditional pacemakers, ICDs and CRT-Ds have been developed and have received FDA approval for use in the United States. The potential hazards of MRI for cardiac device patients include movement of the device, programming changes, asynchronous pacing, activation of tachyarrhythmia therapies, inhibition of pacing output, and induced lead currents that could lead to heating and cardiac stimulation [9], resulting in altered pacing and defibrillation thresholds (DFT), device damage, asystole, arrhythmias, or even death [10]. Although an implantable cardiac device remains a strong relative contraindication to MRI, certain centers have developed protocols for performing MRIs for cardiac device patients [11] without MRI-conditional devices. If an MRI is the only diagnostic imaging option in such a patient, imaging at 1.5 Tesla with appropriate programming and monitoring can often be undertaken safely with careful assessment of the risk–benefit ratio on a case-by-case basis [11–14].

External Defibrillation

In the event of a cardiac arrest or hemodynamically unstable arrhythmia of a patient with an implantable cardiac device, resuscitative efforts should proceed as per guidelines without deviation. Defibrillation or cardioversion can result in permanent damage to the cardiac device; to minimize these risks, the defibrillation pads should be placed at least 10 cm from the pulse generator [15]. Other potential risks of external defibrillation include device reprogramming [16] and myocardial damage at the interface with the lead resulting in an acute rise in threshold [17]. Following defibrillation or cardioversion, cardiac devices should be interrogated formally to insure proper function and programming. Again, the low potential risk of damage to the device should not impede usual and necessary resuscitative efforts for the patient.

Infections

Cardiac device-related infection encompasses a disease spectrum from pocket infection to device-related endocarditis. The clinical manifestations of cardiac device-related infection are protean and can range from pain at the implant site without cutaneous manifestations to minor erythema or swelling of the device pocket (Fig. 196.4A) to overt erosion of the system (Fig. 196.4B) to device-related endocarditis (Fig. 196.4C, Video 196.1) [18,19]. In the absence of bacteremia, systemic manifestations and leukocytosis are rare. Cultures of the device leads yield the highest results and, *Staphylococci* are the pathogens most frequently identified [20]. A high index of suspicion is warranted for a patient with implanted pacemaker or ICD and signs and symptoms of
infection or documented bacteremia. Cardiac device-related infection requires prompt removal of the entire device system for complete treatment unless significant comorbidities preclude extraction [8,18]. Although no specific vegetation size has been established as a contraindication to transvenous extraction, most experts agree that vegetations greater than 3 cm in size are better treated surgically [8]. Patients with device-related endocarditis require a minimum of 6 weeks of intravenous antibiotics and pose a particular challenge with respect to the timing of re-implant in pacemaker-dependent patients.

FIGURE 196.4 Different manifestations of device-related infections. A: Swelling and erythema suggest pocket infection although local signs of inflammation may be absent. B: Erosion of either the lead(s) or device by definition is a manifestation of infection. In this example, the pocket appears swollen with areas of erythema and a pacing electrode (arrow) is seen eroding through the skin at the inferior margin of the pocket. C: Device-related infection could result in bacteremia, vegetations, and sepsis. Here, transesophageal echocardiography demonstrated a large vegetation (arrow) adherent to the atrial pacing lead and seen to prolapse across the tricuspid valve.

Pacemaker Malfunction
Oversensing

Sensing problems are one of the most common causes of pacemaker malfunction (Table 196.3). Oversensing is defined as the sensing of physiologic or nonphysiologic events that should not be sensed. Consequently, oversensing can lead to inappropriate inhibition of pacemaker output (Fig. 196.5). Physiologic events that can be the cause of oversensing include far-field P waves, wide QRS complexes, T waves, and myopotentials, either pectoral or diaphragmatic. Typically, oversensing due to physiologic events can be overcome by decreasing the programmed sensitivity. Nonphysiologic oversensing may be the result of EMI or hardware problems such as loose set-screw or lead dislodgement or fracture and will likely require device revision to correct. Oversensing and failure to pace for a pacemaker-dependent patient can be catastrophic. Application of a magnet over the device will change the device to an asynchronous pacing mode and insure more reliable delivery of pacing until a formal evaluation can be performed.

FIGURE 196.5 Dual chamber defibrillator with evidence of ventricular oversensing. The top panel demonstrates atrial (AP) and ventricular (VP) sequential pacing with the intermittent absence of ventricular pacing stimuli (asterisks) following atrial paced events. The bottom panel represents the intracardiac electrograms from the same device with ventricular oversensing of atrial events (arrows). When intrinsic ventricular conduction does occur
Undersensing

In contrast, undersensing occurs when the device fails to sense intrinsic events. This results the generation of unnecessary pacemaker impulses and “over-pacing.” Undersensing may be a result of alterations in electrogram amplitude of physiologic events or may represent hardware failure. Antiarrhythmic drug therapy, myocardial infarction and metabolic derangements can alter electrogram amplitude transiently or permanently. Undersensing may be potentially corrected by changing the programmed sensitivity. Other etiologies of undersensing are similar to those of noncapture (lead dislodgement, perforation or fracture). Asynchronous pacing modes, due to EMI or battery depletion, can mimic undersensing on surface electrocardiogram.

Noncapture

Noncapture occurs when electrical impulses emitted from the device fail to capture the myocardium. The surface electrocardiogram will demonstrate pacing stimuli without evidence of capture (Fig. 196.6). Loss of capture can be intermittent or permanent, but often necessitates device revision. Causes of noncapture can be divided into changes in capture threshold and hardware malfunction. The capture threshold can rise in the first 4 to 6 weeks following lead implantation due to inflammatory changes at the lead-myocardial border although this has become less relevant clinically with the advent and widespread use of steroid-eluting leads. A rise of capture threshold myocardial fibrosis or infarction near the exit of the pacing stimulus, metabolic derangements (specifically, hyperkalemia, acidemia, or hyperglycemia) and certain medications. Class Ia, Ic, and III antiarrhythmic drugs [21–24] can increase capture thresholds as can mineralocorticoids and hypertonic saline [25]. When the capture threshold exceeds the maximal programmable output, this is termed exit block. Primary hardware problems such as lead dislodgement, perforation or fracture and battery depletion can all result in noncapture. A chest radiograph can help diagnose specific lead issues (Fig. 196.7A to C), as can transthoracic echocardiography (Video 196.2) or other imaging modalities. Formal pacemaker interrogation or magnet application can identify battery depletion.
FIGURE 196.6  Surface electrocardiogram with intermittent loss of ventricular capture. There is appropriate atrial sensing (AS) and tracking as evidence by pacing stimuli at a fixed interval following the P wave but intermittent failure of ventricular output to capture the myocardium (asterisks). Evidence of varying degrees of fusion between intrinsic conduction and ventricular pacing is also observed (arrows).

FIGURE 196.7  Chest radiography can identify
device hardware problems. A: Lead fractures (arrow) can sometimes be seen on X-ray and detailed attention should be paid to the leads along their entire length when a hardware problem is suspected. B: Overt lead perforation can be diagnosed by X-ray. In this example, the entire distal electrode of the defibrillator lead extends beyond the cardiac silhouette (arrow). C: Chest radiography can also confirm lead dislodgement. PA and lateral films of a dual chamber pacing system with the ventricular lead in the right ventricular outflow tract demonstrate dislodgement of the atrial lead. There is evidence of atrial lead dislodgement in the PA view with the distal electrode pointing inferiorly and no visible slack on the lead with absence of the typical “J”-shaped appearance. Atrial lead dislodgement is confirmed by the lateral view that demonstrates the distal electrode of the lead residing below the tricuspid valve annulus.

No Output

The complete absence of pacemaker stimuli despite magnet application suggests complete battery depletion or generator damage. Damage to the generator can occur rarely as a result of direct trauma [26] or external defibrillation [15].

Pacemaker-Mediated Tachycardia (PMT)

PMT refers to any sustained tachyarrhythmia that is dependent upon continued pacemaker participation in the circuit. Classically, the term PMT is used to describe an endless loop tachycardia of dual chamber devices consisting of ventricular pacing, retrograde atrial activation, appropriate sensing and triggered ventricular pacing perpetuating the tachycardia (Fig. 196.8). PMT should be suspected when ventricular pacing occurs at the programmed maximum tracking rate of the device. The PMT circuit can be interrupted with magnet application and the arrhythmia terminated.
Pacemaker-Mediated Tachycardia (PMT). A premature ventricular complex (PVC) occurs in a patient with a dual chamber pacemaker. The PVC results in retrograde conduction back to the atrium that is subsequently tracked by the ventricular lead and incessant tachycardia ensues. Retrograde atrial activation is sensed by the pacemaker because it falls outside the postventricular atrial refractory period (PVARP). One means of eliminating PMT is to extend the PVARP.
DEVICE-SPECIFIC CONSIDERATIONS

Implantable Cardioverter Defibrillator

Electrical Storm

Electrical or ventricular tachycardia (VT) storm is defined as three or more episodes of VT or ventricular fibrillation within a 24-hour period. When a patient presents with electrical storm, suppression of the arrhythmias are of paramount importance. Identifying the trigger can be difficult [27] but attempts should be made to identify and correct potentially treatable causes (Table 196.4). Repeated defibrillator therapy is painful and highly stressful, can cause heightened sympathetic tone and result in early battery depletion, myocardial ischemia/stunning and recurrent ventricular arrhythmias [28]. Thus, initial treatment should consist primarily of sympathetic blockade with β-blockers and anxiolysis with benzodiazepines. Amiodarone is often the antiarrhythmic agent of choice [29]. Refractory cases may require intubation and deep anesthesia [30]; stellate ganglion blockade can be considered for extreme cases [31]. Catheter ablation can be effective for the treatment of electrical storm and should be considered for electrical storm refractory to antiarrhythmic therapies [32].

Ineffective Defibrillation
Successful defibrillation occurs when a critical mass of myocardium is successfully depolarized and depends upon shock vector, lead position, and the electrical milieu (Fig. 196.9). The optimal three-dimensional orientation of the ICD shock vector should deliver energy uniformly throughout the left ventricle. The vector is dependent on the position of the high-voltage coils in the right ventricle (RV) and superior vena cava (SVC)–right atrial (RA) junction and their anatomic relations to the left ventricle. Typically, the RV coil is the cathode and the SVC-RA coil and ICD can form the anode with current traveling from cathode to anode.

**FIGURE 196.9** Defibrillator vector. With a dual coil ICD lead implanted in the RV apex and active ICD can, the shock vector is from the RV coil to the summation of the superior vena caval (SVC) coil and ICD generator (ICD). The SVC coil directs some of the current towards the posterior base of the heart. ICD, implantable cardioverter defibrillator.

Implantable defibrillators can fail to deliver effective defibrillation therapy in certain situations. Elevated DFT can occur as a result of metabolic derangements, myocardial ischemia, pneumothorax, hypoxia, multiple defibrillations, drug therapy, delays in arrhythmia detection, and device hardware malfunction (Table 196.5). Immediate management
should consist of external defibrillation and treatment of potential reversible causes. Long-term management may require device revision or cessation/addition of specific anti-arrhythmic medications.

**TABLE 196.5 Effects of Common Drugs on Defibrillation Thresholds**

**Inappropriate Activations**

Inappropriate activations are common among patients with implantable defibrillators regardless of indication [33] and are associated with significant morbidity and mortality [34,35]. Common causes of
inappropriate activations include SVT, ventricular sensing problems, lead failure, and EMI. The detection algorithms of ICDs are based primarily on heart rate and any ventricular sensed event that exceeds the programmed detection rate will trigger ICD activation. Supraventricular discriminators related to arrhythmia onset, cycle length stability, and electrogram morphology are also programmable but reduce inappropriate activations only slightly [36,37]. Repeated inappropriate ICD activations for hemodynamically stable patients should prompt magnet application or device deactivation with backup external defibrillation available and definitive treatment directed at the underlying rhythm or problem.

The most common cause of inappropriate defibrillator activations is atrial fibrillation although sinus tachycardia and other SVTs can result in inappropriate activations. Surface electrocardiogram and clinical status may aid with the diagnosis when formal interrogation is not immediately available. The device should be inactivated and treatment directed at the underlying atrial arrhythmia. Ventricular sensing problems also result in inappropriate activations when other electrical events (P waves, T waves, and wide QRS) are misinterpreted as a ventricular event. This “double counting” is erroneously interpreted as a tachyarrhythmia and prompts inappropriate ICD activation. Ventricular oversensing may be transient as a result of metabolic derangements (e.g. peaked T waves with hyperkalemia) or may sometimes be successfully eradicated with reprogramming of the device although some sensing problems may require device revision. The S-ICD is particularly susceptible to inappropriate therapies as a result of both ventricular oversensing and undersensing (with a resultant autogain algorithm) as sensing is based upon surface QRS vectors that can change with position and activity. Hardware problems such as lead fracture, insulation break, lead dislodgement or a loose set-screw may result in noise and short ventricular cycle lengths that can be mistakenly detected as VT. The surface electrocardiogram is extremely useful and will demonstrate sinus rhythm or tachycardia at the time of defibrillation. Device hardware problems cannot be overcome with reprogramming. The ICD should be deactivated until the system can be revised. Similarly, EMI can produce noise and result in inappropriate activation.

**Device Management at the End of Life**

Patients with ICDs and end-stage heart failure or other fatal illness warrant special considerations. Successful defibrillation may prolong life but it cannot prevent death. In addition, repeated ICD shocks to a patient with end-stage disease may cause unnecessary pain and anxiety. Defibrillation can be deactivated for ICDs without deactivating
pacemaking functions. Discussions regarding ICD deactivation occur rarely even for patients with do-not-resuscitate orders [38]. It is important that patients and their families understand that deactivation of defibrillator therapies is always an option [39].

Cardiac Resynchronization Therapy (Bi-Ventricular Pacing)

Cardiac resynchronization therapy (CRT) improves symptoms, decreases hospitalizations, assists with reversing remodeling of the left ventricle and reduces mortality among patients with symptomatic heart failure, severe left ventricular dysfunction or mechanical dyssynchrony (QRS > 120 ms) [1,40–43]. Ventricular resynchronization aims to achieve myocardial coordination through left ventricular pre-excitation ideally at the site of latest activation. This can be achieved through an endovascular approach with left ventricular lead placement via coronary sinus cannulation or epicardially with a direct surgical approach (typically via left lateral thoracotomy). Approximately 70% of CRT patients demonstrate clinical improvements including reduction of symptoms [44,45]; fewer show improvement of left ventricular function [46].

Loss of Resynchronization

Achieving resynchronization appears dependent upon not only stimulating the ventricle at the site of latest activation but also providing reliable biventricular pacing. There appears to be a threshold effect of CRT related to the frequency of biventricular pacing. A recent retrospective analysis demonstrated a significant decrease of hospitalizations and mortality at biventricular pacing above 92% [47]. Among CRT responders, loss of resynchronization can result in recurrent symptoms, diminished functional capacity, repeat hospitalization, and significant hemodynamic alterations. Although formal device interrogation is necessary to assess the degree of biventricular pacing over the long-term, careful observation of the telemetry monitor often can provide significant insights. Similarly, the 12-lead electrocardiogram can identify the site of ventricular stimulation and can be used to detect loss of biventricular pacing (Fig. 196.10A,B). Atrial arrhythmias with intact ventricular conduction exceeding the programmed lower rate of the CRT device are the most common reason for failure to achieve sufficient resynchronization. Other potential reasons for suboptimal biventricular pacing include elevated pacing threshold, lead fracture, or lead migration to an unfavorable location. Common reasons for a lack of response to CRT are lead location, suboptimal programming and underlying narrow QRS [48]. If the left ventricular pacing lead is not
stimulating a late activation site in the basal posterolateral left ventricle, the degree of biventricular pacing is irrelevant. The electrocardiogram and chest radiograph are useful for identifying issues with left ventricular lead placement.

**FIGURE 196.10** Electrocardiographic assessment of pacing site. A: Right ventricular apical pacing with left bundle branch morphology and superior frontal plane axis. B: In contrast, biventricular stimulation with right bundle morphology in V1 and QS waves in leads I and aVL.

**Summary**

In the modern era, patients with implantable pacemakers, defibrillators, and cardiac resynchronization devices are increasingly commonly
admitted to the care of an intensivist. Attention to and understanding of the implanted device as a critical portion of the patient’s acute care is warranted. Early involvement of electrophysiologist colleagues for the care of critically ill patients especially with device malfunction or infection is prudent.

In 2015, the American Heart Association estimated that there were 5.7 million American adults with heart failure (HF). Projections estimate that number will grow to >8 million adults by the year 2030. Each year, there are an estimated 650,000 new cases of HF, 1 million annual hospital admissions, and 300,000 deaths as a result of HF [1,2]. In 2012, the total cost for HF was estimated to be almost $31 billion with an expected rise to $70 billion by 2030—$244 for every US adult [3]. The subset of patients with systolic HF is estimated to be 3 to 3.5 million, and of those, about 10% or 200,000 to 300,000 will have advanced HF [1–3]. The mortality from HF remains very high, approximately 50% at 5 years. Those who are inotrope dependent have a mortality of 78% at 6 months and nearly 90% at 1 year. In comparison, the 1-year mortality for pancreatic cancer is 80% [4,5].

Cardiac transplantation still represents the most definitive therapy for advanced HF with estimated survival of 85% at 1 year and 70% at 5 years. The current generation of continuous flow left ventricular assist devices (LVADs) have an estimated survival of 80% at 1 year and 70% at 2 years (Fig. 197.1) [6]. The use of an LVAD pretransplant has traditionally conferred an increased risk posttransplant, but with modern continuous flow devices, that is no longer the case [7]. Given that there are approximately 2,200 donor hearts available each year targeted to eligible candidates, the role of long-term mechanical circulatory support (MCS) has become a fundamental tenet of advanced HF treatment. The proper application of MCS requires knowledge of the underlying mechanism of HF, understanding of the potential benefits and limitations of both
medical and device therapy, familiarity with the full range of devices available for support, and, perhaps most critically, careful selection of the appropriate timing for intervention.

**FIGURE 197.1** Parametric survival curve and associated hazard function with the 70% confidence limit for survival after implantation of a continuous flow LVAD or BiVAD. The number of patients at risk during each time interval is indicated below. LVAD, left ventricular assist device; BiVAD, biventricular assist device.

**MECHANICAL CIRCULATORY SUPPORT**

Over the past five decades, MCS technology has evolved substantially from partial temporary support with intra-aortic balloon counterpulsation to a broad array of ventricular assist devices (VADs) capable of providing long-term complete support for one or both ventricles. The first successful implantation of a paracorporeal LVAD was performed by Dr. DeBakey in 1966 and supported a 37-year-old woman for 10 days. Initial Food and Drug Administration (FDA) approval was granted to the first VAD system in 1995 [8]. Through the 1990s, extensive experience with bridging patients to transplantation spurred the
evolution from bulky extracorporeal devices to smaller, implantable designs, which allowed patients to be discharged from the hospital with substantial improvements of functional status and quality of life. In 2008, the first modern-generation continuous flow LVAD, the HeartMate II (HM II; Thoratec Corp., Pleasanton, CA, USA) was approved by the FDA as a bridge to transplantation (BTT) and then received approval for a destination therapy (DT) indication in 2010 [9]. More recently, a series of landmark trials have demonstrated the superiority of continuous flow LVADs with increased survival, enhanced quality of life, and fewer adverse events, compared to the prior generations of larger pulsatile pumps [10–13]. As of November 2015, the longest continuous support that a patient has received from an LVAD was 11.5 years, requiring three HM II pumps because of driveline infections. The longest continuous support on a single pump (HM II) is 10.3 years (Thoratec Corp., personal communication, 11/25/2015).
Continuous Flow LVAD Technology

Continuous flow LVADs have become the dominant technology, primarily because of their smaller size and greater durability. Continuous flow pumps consist of an inflow cannula, outflow cannula, and a single impeller that spins continuously. Current generation devices are valveless pumps that use a magnetic field to spin a single impeller that is supported by mechanical, hydrodynamic, or magnetic bearings (Fig. 197.2) [14]. Axial flow pumps direct blood flow parallel to the axis of rotation, whereas centrifugal flow pumps have the impeller direct flow perpendicular to the axis of rotation [15]. The impeller’s position may be maintained by mechanical bearings (St. Jude, HeartMate II), hydrodynamic thrust bearings (Heartware, HVAD), or full magnetic levitation (St. Jude, HeartMate 3).

![Schematic of an LVAD system.](image)

**FIGURE 197.2** Schematic of an LVAD system. Components include a surgically implanted pump that works in parallel with the native heart via an inflow cannula to the left ventricle and an outflow graft to the
ascending aorta, a percutaneous driveline, a system controller, and electrically powered batteries with a life span up to 12 hours (A). Features of continuous flow axial (B), centrifugal (C), and mixed design pumps, where the pump is axial but blood exits perpendicular to the inflow like in centrifugal pumps (D), are also shown. LVAD, left ventricular assist device.

One important concept regarding axial and centrifugal flow devices is that of hydrodynamic performance, which is demonstrated by pump head curves (Fig. 197.3). A pump head curve illustrates the relationship between pump flow and pressure difference across the inflow (left ventricular pressure) and outflow (aortic pressure) of a pump at a set speed. When the pressure differential across the pump is lower, such as during ventricular systole, pump flow is greater. Axial flow pumps have a steeper relationship between flow and head pressure than centrifugal flow pumps; thus, the same change in pressure across the pump will result in smaller changes in flow across the cardiac cycle and hence less pulsatility.

**FIGURE 197.3** (A) Representation of the systemic AoP and LVP relationship is shown during rotary LVAD support in a failing ventricle. Comparison of (B) centrifugal flow and (C) axial rotary pump performance characteristics are shown as pressure differential across pump inlet and outlet in mm Hg and pump flow in L/min. (D) Representative centrifugal and axial rotary pump flow waveforms during rotary LVAD support in a failing ventricle are compared. AoP, arterial pressure; LVP, left ventricular pressure; LVAD,
Hemodynamics

As the left ventricle (LV) begins to fail, cardiac output falls and intracardiac filling pressures rise. The main goals of MCS are to decompress the failing ventricle and augment systemic perfusion [6]. Mechanical unloading of the LV leads to a decrease of the severity of mitral regurgitation, less pulmonary congestion, and a reduction of pulmonary hypertension, all of which, in turn, can result in improved right ventricular (RV) function. Partial support pumps provide several liters of flow to augment the reduced native ventricular contribution to the total output, whereas full support pumps provide upward of 7 to 10 L per minute of flow with the native heart contributing little to the total output. Restoration of forward flow and the normalization of filling pressures also reduces neurohormonal activation, with attendant benefits on cardiorenal function [16].

Biological

The hemodynamic benefits of MCS with an LVAD are also associated with biologic changes such as improved β-adrenergic responsiveness as well as favorable myocardial structural, functional, and contractile changes. LVAD support has been shown to alter gene expression that is linked to improving the β-receptor density and responsiveness that is downregulated during chronic HF. Likewise, studies have shown improved calcium handling properties, as well as a reduction of maladaptive neurohormonal upregulation. In vivo, mechanical unloading with an LVAD is known to be associated with alteration of gene and protein expression within the cardiac myocyte, a reduction of nuclear size and DNA content, and reductions of fibrosis and collagen content within the cardiac extracellular matrix [17].
SELECTION OF APPROPRIATE MECHANICAL SUPPORT

The clinical application of MCS grew from early experience as temporary support in the operating room to providing support for years as an alternative to transplant. A broad array of different ventricular support devices is now available, and all currently FDA–approved durable devices included in INTERMACS are listed in Table 197.1. In general, the devices may be configured for isolated left ventricular (LVAD), right ventricular (RVAD), or biventricular (BiVAD) support and for short-term (bridge to decision [BTD], recovery, or transplant), or long-term (DT) support. Some devices are extracorporeal or paracorporeal in location, with cannulae traversing the skin allowing for inflow and outflow of blood, whereas others are totally implantable with the pump and the cannulae housed in the thoracic and/or abdominal cavity with only a single percutaneous line supplying the power and providing the connections to the external control systems.

Cannulation of Ventricular Assist Devices

VADs are typically implanted in parallel with the native right- or left-sided circulation. For long-term LVADs, the pump inflow is from a cannula placed directly into the LV apex, and the pump outflow is a cannula that is anastomosed to the ascending aorta just distal to the aortic valve (AV). Pulsatile systems typically have valves in the inflow and outflow cannulae, whereas continuous flow devices do not. RVADs typically have inflow from the right atrium, or alternatively from the cavae or femoral veins, rather than the RV apex, because RV apical cannulation typically provides less reliable flow. Outflow is directed to the main pulmonary artery just distal to the pulmonic valve through either direct or transvenous cannulation.

The LV is continuously and actively unloaded; therefore, the LV less frequently fills to the point where it can eject blood during systole. As a result, patients often have minimal contribution from their native ventricles leading to a greatly reduced pulse pressure. Historically, the blood pressure has been referred to as a mean blood pressure; however, this terminology is currently under scrutiny because research is demonstrating that there is significant heterogeneity in the pulse pressure that patients are able to produce, often under dynamic circumstances of preload and afterload [18]. Based on clinical experience, the pulse pressure may vary from 0 to greater than 25 mm Hg. Patients supported with continuous flow LVADs often require Doppler ultrasound to assess their blood pressure owing to the lack of pulsatility. As previously mentioned, continuous flow pumps are generally one of two major types: axial or centrifugal flow. The HM II is an axial flow LVAD with typical operating speeds ranging from 9,000 to 10,000 × g and is approved for both BTT and DT. The Heartware HVAD is a centrifugal flow LVAD with hydrodynamic bearings and is approved for BTT and is currently undergoing study for a destination therapy clinical trial. Continuous flow pumps are the preferred technology, compared to pulsatile pumps, because of demonstrated superior survival rates and lower rates of adverse events.
VAD support can be divided into four device strategies at the time of implant: (1) BTT, (2) DT, (3) BTD, and (4) bridge to recovery (BTR). As the field has evolved, DT has become the most common indication for durable MCS with nearly 46% of implants assigned as DT in 2014, whereas 30% were listed as BTT candidates. BTR remains uncommon at 1% to 2%. Approximately 20% to 25% are assigned as BTD [6].

The survival following cardiac transplantation has been excellent with a median survival of almost 11 years [7]. With increased numbers of patients waiting for a cardiac transplantation and little to no growth in organ availability, bridging patients with an LVAD has become increasingly common with 37% of patients having an LVAD at some point before transplantation [7]. DT specifically refers to the long-term use of an LVAD as an alternative therapy to transplantation for patients who are ineligible because of contraindications. This is the largest growing VAD indication having increased to almost half of all indications as of 2014 [6]. As of 2014, almost one in four patients were designated as BTD for an LVAD. The rationale for this designation is often owing to a temporary contraindication to transplantation listing such as end-organ function that is expected to improve after mechanical correction of the maladaptive mechanisms of HF (e.g., pulmonary hypertension, cardiorenal syndrome, etc.). BTR is a hotly contested topic with incidences ranging as low as <1% to as high as 20%, in highly selected cohorts. In the HM II trials, 1% to 2% of patients were explanted owing to LV recovery. LV recovery is most likely to occur among young patients with nonischemic cardiomyopathies of <1-year duration [19,20].
UNIVENTRICULAR VERSUS BIVENTRICULAR SUPPORT

Selection of the appropriate device for MCS depends initially on the type of support that is required. Most patients presenting with acute HF or shock predominantly have LV failure and may be candidates for isolated LV support with an LVAD. Successful LVAD implantation relies heavily on confirmation of adequate native RV function, because RV function is required for LVAD filling. For patients with concomitant, severe RV dysfunction, biventricular support may be necessary. Although recent experience suggests that selected BiVAD patients can be successfully discharged to home, 1-year survival with a BiVAD is 50%, which remains markedly less than the 80% 1-year survival with an LVAD alone. This discrepancy is partially owing to greater severity of illness and end-organ dysfunction among patients presenting initially with biventricular failure [6,21]. Because there is no approved BiVAD device for DT, this therapy is only available for patients who are potentially candidates for cardiac transplantation. Those patients with prolonged shock, giant cell myocarditis, refractory ventricular tachyarrhythmias, or a high likelihood of postoperative right ventricular failure (RVF) may be considered for BiVADs. Even with the current generation of continuous flow LVADs, RVF complicates 10% to 40% of LVAD implants, underscoring the need for careful assessment of RV function prior to VAD implantation [22]. At select centers, explant of the native heart and implantation of a total artificial heart may provide an alternative to the use of BiVADs [23].
CANDIDATE SELECTION FOR LONG-TERM MCS THERAPY

Patient selection and timing of implantation are critical features of successful mechanical support [6]. Guidelines for the clinical management of the HM II was published in 2010. In 2013, The International Society for Heart and Lung Transplantation (ISHLT) published guidelines for the selection, implantation, and device management for MCS patients [24,25]. The most salient recommendations are summarized below.

Illness Assessment

The criteria for use of MCS as BTT are based on several factors that include being a cardiac transplantation candidate with impaired systemic perfusion and end-organ function. In general, a patient must have a cardiac index less than 2.0 L per minute with evidence of elevated filling pressures after optimal medical management. Other reasons to use MCS as BTT include an expected long wait list time owing to uncommon blood type and/or larger body size. Additional factors include a worsening clinical status with evidence of new or worsening end-organ dysfunction such as renal or hepatic dysfunction, prolonged coagulation levels, and progressive HF.

In contrast to BTT, the Centers for Medicare and Medicaid Services adopted the entry criteria for the REMATCH trial as reimbursement requirements for DT:

1. New York Heart Association (NYHA) functional class IV or stage D HF symptoms, despite use of maximally tolerated optimal medical therapy for at least 45 of the last 60 days, or have been intra-aortic balloon pump (IABP) dependent for 7 or more days, or intravenous (IV) inotrope dependent for 14 or more days;

2. Left ventricular ejection fraction less than 25%; and

3. Functional limitation with a peak oxygen consumption \( \leq 14 \) mL/kg/min, unless on inotropic therapy, IABP support, or physically unable to perform the test. In general, any patient who is inotrope dependent and expected to have a sufficient 1- to 2-year survival with a reasonable quality of life should be referred for consideration of VAD therapy.
Several predictive models, such as the Heart Failure Survival Score and the Seattle Heart Failure Model, exist to help clinicians estimate survival [26,27]. However, these models were derived from a less critically ill population and have not been validated for patients who are being considered for MCS [28]. Older models also exist but are limited by describing risk attributable to an antiquated device [29,30] or were derived from a previous era of MCS support [31]. The HM II Risk Score was derived and validated within 1,122 patients who received continuous flow HM II devices and identified the following factors as being associated with higher mortality: increasing age, hypoalbuminemia, renal dysfunction, coagulopathy, and LVAD implantation at less experienced centers [32].

INTERMACS has provided a means by which to assess risk for patients undergoing MCS by their preimplant acuity of illness. INTERMACS established seven different profiles for patients being implanted with MCS from advanced NYHA class III patients, through inotrope dependence, to critical cardiogenic shock despite maximal medical management (Table 197.2) [33]. Data from INTERMACS have shown that risk stratification based solely upon the preimplant profiles does indeed predict outcomes when applied to both pulsatile and continuous flow devices [6,34–36]. There is a significant survival difference at 1 year between those who were INTERMACS Level 1 (76%) versus 2 to 3 (80%) or 4 to 7 (82%). Notably, INTERMACS Level 1 primarily confers an early hazard for mortality with a sharp drop of survival occurring within the first 3-months postimplantation.

Unfortunately, all predictive models have had limited use in clinical practice because of their inability to accurately predict outcomes across a heterogeneous HF population. Recently, a Bayesian model was developed to predict survival with some of the important predictor variables for mortality, including intervention within the last 48 hours (such as extracorporeal membrane oxygenation, dialysis, and ventilators), events during the hospitalization, prior cardiac operations, INTERMACS profile, renal dysfunction, and implant year [37]. A recent study of DT patients from the INTERMACS cohort developed a predictive model to determine a composite outcome of mortality and quality of life. Notably, one in three patients had a poor outcome at 1 year, which was mostly driven by death. The most significant predictors of a poor outcome at 1 year were older age, lower baseline quality of life scores, larger body mass indices (BMIs), INTERMACS profiles 1 and 2, and a history of solid organ cancer. Still, the model was not able to broadly separate patient risk [38]. In summary, LVAD prediction risk models can help guide clinicians’ decision-making and help to calibrate patients’ expectations; however, they can not be solely relied upon for these complex decisions. Comorbidities that may be life-threatening at the time of implantation or postoperatively should be carefully excluded prior to MCS candidacy. In general, the most common contraindications to transplant in DT patients are advanced age, renal dysfunction, high BMI, pulmonary hypertension, and other significant comorbidities [34].

**Right Ventricular Function**

RVF remains a common complication and important cause of morbidity and mortality after LVAD implantation [22]. Most LVAD candidates have some degree of RV dysfunction prior to implant, rendering the assessment of RV function and prediction of RVF paramount to achieving good outcomes.

RVF is defined by INTERMACS as documented elevations of central venous pressure (CVP) and its manifestations, such as edema, ascites, or worsening hepatic or renal dysfunction. Severe RVF is defined as the need for prolonged postimplant inotropes, inhaled nitric oxide or IV...
vasodilators continued beyond postoperative day 14, or a requirement for RV mechanical support. Patients must meet the criteria for RVF mentioned above as well as any of the following: (1) need for inotropes at any time since last evaluation, (2) two or more readmissions requiring treatment for RVF, (3) RVAD support, or (4) death as a result of RVF [39].

LV mechanical support is generally beneficial for RV function, with chronic unloading of the LV resulting in a reduction of pulmonary pressures and RV afterload with resulting improved RV function. However, there may be deleterious effects of an LVAD on RV function, particularly when RV function is marginal. Profound unloading of the LV, particularly with continuous flow devices, can result in shifting of the septum away from the RV and, thus, decrease the septal contribution to RV output [40]. LV contraction contributes 20% to 40% of RV output [41]. The RV may also struggle to accommodate the increased venous return as a result of the improved cardiac output from the LVAD [40,42]. In addition, tricuspid regurgitation can intensify in the setting of a known regurgitant valve that may be further tethered by the septal shift with increased RV volume from venous return. Lastly, perioperative volume resuscitation can exacerbate RV dilation and TR [43]. The same processes that lead to LV dysfunction can also cause RVF [42]. Lastly, other processes that may exacerbate pulmonary hypertension, such as blood product-induced lung injury, hypoxic lung disease, sleep apnea, chronic thromboembolic disease, or pulmonary vasculopathy, can also contribute to RV dysfunction.

Similar to the overall patient selection process, investigators have developed risk scores to attempt to predict RVF among LVAD candidates [44–51]. Identified clinical and biochemical risk factors for RVF include female gender, nonischemic etiology, prior cardiac surgery, need for an IABP, inotrope dependency, vasopressor use, need for mechanical ventilation, and elevated renal/liver biomarkers. Echocardiographic assessment of RV function has been aggressively studied with various predictors identified: tricuspid annular motion <7.5 mm [52], spherical RV geometry [53], severe TR [53], increased RV to LV end-diastolic diameter ratio [54,55], RV fractional area contraction, and left atrial volume index [56], as well as some LV parameters [57]. Assessment of RV function is problematic owing to its complex three-dimensional geometry [58]. The current imaging gold standard to assess the RV is cardiac MRI, but data are lacking, often owing to ferromagnetic contraindications of advanced HF patients, such as mechanical valves, pacemaker, and defibrillators. Multiple hemodynamic alternations have been associated with RVF but lack consistency. An elevated CVP or CVP to pulmonary capillary wedge pressure ratio has been reported as risk factors in multiple studies [44,47,49,59]. Despite the aforementioned risk factors,
few exist across multiple studies, and the risk scores also lack consistent validation.

The treatment goals for RVF are similar to LV failure—decrease excess preload and afterload, while increasing contractility. RV preload should be reduced with aggressive diuresis and, if needed, mechanical volume removal if there is a renal limitation to diuresis. The dysfunctional RV may need slightly more preload to maintain output, but a goal should be to reduce the RA pressure to at least less than 15 mm Hg, and preferably as low as tolerated [20]. If inotropes are needed, milrinone, an ionodilator, offers theoretical benefits for RV support in the setting of concomitant pulmonary hypertension owing to its vasodilatory properties [60]. Afterload is addressed through strategies to reduce elevated pulmonary pressures. Reducing the left-sided filling pressures is the first and most important therapeutic targets and can be accomplished through a combination of diuresis, inotropy, IABP, and even a temporary LVAD. Patients must have adequate oxygenation to avoid hypoxic pulmonary vasoconstriction and, if intubated, positive end-expiratory pressure should be minimized [61]. Nitric oxide may be considered for the intubated patient, but such patients may be too ill to consider LV support alone. There is little evidence for the use of other vasodilators such as prostaglandins, preoperatively, and some evidence that such therapies may be deleterious in the setting of LV failure [62]. Consideration may be given to surgical repair of moderate to severe tricuspid regurgitation, but this remains controversial [24,63]. The management of RV function is outlined in Table 197.3.

LV, left ventricle; IABP, intra-aortic balloon pump; CT, computed tomography; RV, right ventricle; CVP, central venous pressure; ASD, atrial septal defect; VSD, ventricular septal defect; HF, heart failure; BiVADs; AI, aortic insufficiency; AV, aortic valve.
Arrhythmias

Ventricular tachyarrhythmias are common in the setting of acutely decompensated HF. Many patients with chronic HF will have a history of ventricular tachycardia or have an implantable cardioverter defibrillator (ICD) with or without resynchronization therapy [58]. Aside from their impact on the patient’s stability in the acute phase of their presentation, the persistence of ventricular tachyarrhythmias has implications for outcomes after mechanical support. The presence of sustained ventricular tachycardia or ventricular fibrillation during LVAD support can substantially affect RV function, particularly when it is borderline. Although ventricular tachyarrhythmias are not typically lethal in the setting of LVAD support alone, they may result in lower pump output, hypotension, and recurrent symptoms. For patients with an ICD, they may also result in frequent ICD discharges. Preoperative ventricular tachyarrhythmias in the setting of substantially elevated filling pressures or acute ischemia often resolve after MCS as the HF state resolves. However, patients with treatment-refractory and recurrent ventricular arrhythmias in the presence of an untreatable substrate are at higher risk of recurrence or persistence of these arrhythmias post-MCS and should be considered for biventricular support or a total artificial heart [24]. Patients with medically refractory atrial tachyarrhythmias may benefit from ablative procedures prior to long-term MCS [24].

Valvular Disease

In the presence of an LVAD, aortic insufficiency (AI) leads to a circulatory loop with a portion of LVAD output regurgitating through the AV into the LV and back again through the device, limiting effective forward flow and ultimately leading to organ malperfusion and increased LV diastolic pressures. The prognosis of moderate to severe AI of LVAD patients is generally poor and leads to a higher rate of AV replacement and potentially reduced survival. Current, evidence-based guidelines for valvular repair all have a level of evidence C classification [24]. Preoperatively, assessment of the degree of AI should be performed with echocardiography. If more than mild AI is present, consideration should be given to surgical intervention during device implantation such as a central aortic suture (commonly referred to as the “Park stitch”), bioprosthetic replacement, or oversewing the AV [24]. With adequate decompression by the LVAD, the LV generates very little effective forward flow, which often results in minimal AV opening. Among patients with mechanical aortic prostheses, this lack of flow across the valve may result in the formation of thrombosis and subsequent embolism [64]. Consequently, guidelines recommend that mechanical AVs be replaced
with tissue valves at the time of surgery or oversewn [24]. Mitral regurgitation essentially resolves post-MCS with adequate LV decompression, but significant mitral stenosis can impede LVAD filling and should be addressed at the time of implantation [65]. A summary of other valvular recommendations can be seen in Table 197.3.

Other Cardiac Abnormalities

Per the ISHLT guidelines, atrial septal defects and patent formaen ovales should be closed at the time of MCS implantation. In the setting of a ventricular septal defect, an LVAD alone is not recommended without concomitant repair of the VSD, if otherwise indicated by guidelines. LV thrombus can form in the setting of acute ischemia or with chronic LV dysfunction. Such thrombi are usually located in the LV apex, which is the site of cannulation for the LVAD. Echocardiography or computed tomography (CT), with contrast when needed, should be used to screen preoperatively. Although the ventricle is routinely inspected before insertion of the cannula, knowledge of the presence of thrombus preoperatively is important because retained thrombus may systemically embolize or, worse, be sucked into the impeller of a continuous flow pump, possibly resulting in pump failure. For patients with congenital heart disease, it is important to establish the anatomic position of the systemic ventricle and aorta as well as the type and location of any previous corrective surgeries. Complex congenital heart disease may necessitate placement of the pump or inflow/outflow cannulae in atypical positions. The presence of aortic root disease should be screened for with a CT scan prior to implantation, particularly when there is a history of vascular and/or coronary artery disease [24,25].

Noncardiac Preoperative Assessment

Other chronic medical conditions, many of which are exacerbated by acute HF, should be optimized if possible prior to implantation of long-term MCS. Patients must be assessed for signs of infection, and when diagnosed, treated aggressively prior to implant. Active infection at the time of implantation can be catastrophic because bacteremia can result in device infection which may be chronically suppressed but rarely cured with antibiotic therapy. If the pump or the pump pocket becomes infected, the most definitive recourse is urgent cardiac transplantation, when indicated, because device exchanges in these situations often result in recurrent infection [66]. ISHLT guidelines recommend documented clearance of bacteremia for at least 5 days with at least a prior 7 day course of appropriate antimicrobial therapy prior to LVAD implantation [24]. Preimplant renal dysfunction is very common, with almost 90% of
patients having at least mild kidney dysfunction. The presence of renal dysfunction often negatively impacts patients’ advanced therapies options [67]. Many of the causes of the renal dysfunction are often related to the hemodynamic perturbations of HF (poor renal perfusion, renal venous congestion, high doses of diuretics, the adverse neurohormonal milieu of HF, etc.); fortunately, substantial early improvement of renal function often occurs post-MCS implant [67–71]. Still, there is a population of patients with worsening renal function post-MCS implantation associated with morbid outcomes, and there is no effective clinical algorithm to risk stratify those patients. Preoperatively, it is recommended to optimize HF management with inotropy, IABP, or even temporary mechanical support when necessary to help promote renal recovery. The need for renal replacement therapy post-MCS remains a highly morbid event, likely reflecting the level of illness entering the surgery [72].

Intrinsic pulmonary disease also has a number of implications for long-term MCS. Advanced lung disease impacts mortality and morbidity from the implantation surgery itself as well as the ability to rehabilitate and attain a good postoperative functional status. Hypoxic pulmonary vasoconstriction from intrinsic lung disease may also exacerbate preexisting pulmonary hypertension. Patients with severe obstructive or restrictive pulmonary disease are not candidates for long-term MCS [65]. Though there are no strict pulmonary function testing exclusion criteria, outcomes are often unfavorable when the forced expiratory volume at 1 second, forced vital capacity, and carbon monoxide diffusing capacity are all less than 50% of predicted values and LVAD eligibility should be scrutinized [25]. Intubation and mechanical ventilation prior to implantation are also strong risk factors for mortality and RVF [6,47].

Preoperative hepatic dysfunction, most notably elevated bilirubin levels and low albumin levels, have been associated with poor outcomes [6,73]. Hepatic dysfunction is occasionally a result of shock from acute decompensation, but chronic occult hepatic dysfunction is not uncommon with chronic HF, especially in the setting of poor RV function with persistently high right atrial pressures or those with Fontan circulation. These patients may have significant hepatic dysfunction without substantial baseline abnormalities of transaminases or total bilirubin. There should be a low threshold to screen such patients with hepatic Doppler ultrasonography, CT, or even biopsy to assess hepatic architecture for signs of cirrhosis. If there is evidence of cirrhosis, then early involvement of a hepatologist and liver biopsy is suggested. The
distinction between hepatic dysfunction secondary to chronic hepatic congestion as a result of RVF and cirrhosis is paramount, because the former will likely improve with MCS support (LVAD or BiVAD) and the latter will not. Patients with cirrhotic physiology do very poorly and, in general, are not eligible for LVAD therapy. The Model for End Stage Liver Disease (MELD) score has been used as a risk stratification score, and it has been shown to predict mortality, perioperative bleeding, RVF, renal failure, and postoperative infections [74]. The utility of the MELD score for the MCS population lies in its incorporation of multisystem dysfunction and coagulopathy. Specific interventions to optimize hepatic function preoperatively include preload and afterload reduction to decrease right atrial pressure and pulmonary vascular resistance and treatment of viral infections. Temporary MCS may be considered when medical therapy is insufficient. Vitamin K supplementation and nutritional optimization should be considered when significant coagulopathy exists to help mitigate perioperative bleeding. Bleeding, especially from the gastrointestinal tract, is recognized as one of the most common adverse events of continuous flow devices and is associated with a high morbidity [75–77]. There is a high rate of gastrointestinal arteriovenous malformations (AVMs) and acquired von Willebrand deficiency among patients supported with continuous flow devices, which may be secondary to a combination of low flow pulsatility as well as shear stress on blood components [76,78–81]. Given the need for systemic anticoagulation with LVADs, patients with recurrent gastrointestinal bleeding should be evaluated by gastroenterology for treatable sources of the bleeding. If there is no remediable source of bleeding, then the patient’s eligibility for MCS should be questioned.

Minimizing perioperative bleeding surrounding MCS implantation can also be achieved through careful management of antiplatelet and anticoagulant therapy. Ideally, antiplatelet agents should be stopped at least 5 days prior to implantation [25]. On the contrary, patients with a history of thrombophilia should undergo a hypercoagulable workup, given the elevated risk of pump thrombosis.

Extensive carotid or peripheral vascular disease may increase the risk of extracardiac vascular events such as mesenteric ischemia, lower extremity ischemia, and neurologic events, and must be evaluated appropriately with preoperative noninvasive testing. Notably, patients with peripheral vascular disease have been excluded from many of the MCS trials. Screening should consist of carotid dopplers, ankle-brachial index testing, and abdominal ultrasound or CT abdominopelvic testing for those with risk factors. Among patients who present acutely, nutrition is not often a pressing issue, but nutritional impairment among patients with chronic HF can be quite profound, and low BMI is a risk factor for poor outcomes [66]. Poor nutrition impacts T-cell function and is another
risk factor for infection and poor postoperative wound healing. For patients at nutritional risk, supplemental feeding may be of some use, but should not delay implantation when MCS is indicated. Obesity is also common among patients with HF but is not a contraindication to MCS. In the HM II trials, a BMI >40 kg per m² was an exclusion criteria. Observational studies have mixed results regarding an association of obesity with poor outcomes [6,38,82–84]. Based on data from INTERMACS, the largest registry available, obesity incrementally portends a risk for mortality and poor quality of life [38]. Based on the authors’ clinical experience, obesity increases the risk of driveline complications owing to mechanical stress. Though there are small case series reporting on simultaneous sleeve gastrectomies and LVAD implantation for patients with class III obesity (BMI ≥ 40 kg per m²) with both promising weight loss results and medium-term outcomes, these are preliminary experiences in need of more observational and clinical trial data [85,86]. Clinical prudence should be used when evaluating MCS eligibility for those with class II or higher obesity (BMI ≥ 35 kg per m²) [24].

In general, the estimated life expectancy of patients with a history of malignancy will guide their candidacy for MCS. If they have an active or recently treated cancer with a reasonable life expectancy (e.g., >2 years), then DT MCS is an option. If their cancer is in long-term remission, they may be candidates for MCS as BTT or DT. However, if their life expectancy is <2 years, then long-term MCS is not recommended [24].
COMPLICATIONS OF MECHANICAL CIRCULATORY SUPPORT

Though VAD technology and increased clinical experience have led to improved outcomes over time, adverse events still occur and account for considerable morbidity and mortality [6]. The overall 1-year adverse event rate is lower in the most recent era (2012 to 2014) of MCS devices. Nevertheless, certain events such as hemolysis, renal dysfunction, stroke, and respiratory failure have increased in the current era [6]. Based on the INTERMACS registry, the most common adverse event rates (events/100 patients months) in the first year postimplant are bleeding (7.8), infection (7.3), arrhythmia (4.1), respiratory failure (2.7), and stroke (1.6) [6]. (These are based on standard definitions of adverse events, which can be found on the INTERMACS website) [39]. In addition, acquired AI occurs frequently with an incidence of >30% at 3 years [87].
EARLY POSTOPERATIVE HEMODYNAMIC MANAGEMENT

Per the 2013 ISHLT guidelines, early postoperative hemodynamic management recommendations are listed in Table 197.4. An algorithm for low pump output treatment is presented in Figure 197.4. A systematic approach to treating hypotension has been proposed (Fig. 197.5) [24].

**Bleeding**

Bleeding is the most common adverse event after VAD implantation with transfusions, leading to a higher risk of infection, allosensitization, and acute lung injury [88,89]. Though major bleeding episodes can often be managed successfully with transfusions and/or procedures, the 1-year mortality rate is significantly higher than for those without bleeding episodes. The degree of perioperative bleeding can be affected by preexisting coagulopathy, liver congestion, and prior sternotomies or other concomitant corrective surgeries at the time of MCS. Most current generation devices require anticoagulation with heparin after postoperative bleeding subsides and then chronically with oral anticoagulation and, depending on the center and device, an antiplatelet agent(s).
Continuous flow pumps present a unique risk for gastrointestinal bleeding. The high shear stress from the impeller on blood can cause destruction of large multimers of von Willebrand factor (vWF), which results in a picture of acquired von Willebrand’s disease [79,90,91]. Although bleeding risk is mostly manifest from gastrointestinal AVM, it is unknown if the loss of vWF multimers results in bleeding from preexisting AVMs or the lack of pulsatile flow predisposes to the development of AVMs [76,79]. Although most patients have a demonstrable loss of vWF multimers, only a minority of patients develop bleeding. For those who are awaiting cardiac transplantation, bleeding requiring transfusion carries the additional risk of sensitization to human leukocyte antigens that may limit the pool of suitable donor hearts [92].

Anticoagulation and antiplatelet therapy should be initiated postoperatively in the intensive care unit setting and targeted to device-specific goals. Though there is some institutional variation, the recommended international normalized ratio (INR) goal for the two most common continuous flow devices (HM II and HVAD) is 2.0 to 3.0. Chronic antiplatelet therapy with aspirin (81 to 325 mg daily) should be considered in addition to warfarin [24].

If bleeding occurs, it should be immediately evaluated and anticoagulation should be lowered, discontinued and/or reversed as needed [24]. In the setting of clinically significant bleeding with an elevated INR, the ISHLT MCS guidelines recommend reversing anticoagulation [24]. During a sentinel gastrointestinal bleed, gastroenterology consultation should assist with management, and patients should at least undergo endoscopy and colonoscopy. If the evaluation does not reveal a source, subsequent diagnostic testing may include small bowel evaluation (capsule endoscopy or push enteroscopy), tagged red blood scan, or angiography [24]. Sometimes despite extensive evaluation, no source of bleeding can be identified or is not amenable to therapy. In those cases, reevaluation of the goals and necessity of anticoagulation and antiplatelet agents should be considered.

Infection

The most common time for blood-borne infections related to VADs occurs within the first 30 days after implantation, although infections also arise later, just at a lower risk [93]. Risk factors associated with VAD infections consist of the severity of preoperative illness, biventricular support, age, and higher blood urea nitrogen levels [94]. Aside from the infection risks associated with surgery and indwelling lines postoperatively, there are additional chronic risks associated with the presence of the VAD itself and the associated driveline or cannulae. However, sepsis from any source can result in seeding of interior of the
VAD or its components, which may necessitate more urgent and higher risk cardiac transplantation or even device replacement [95]. Vegetations on LVAD prosthetic valves may also be a source of thromboembolism [96]. The education of patients and their caregivers about percutaneous lead and exit-site care with aseptic technique for dressing changes is crucial.

Several recommendations can be made for the evaluation of MCS patients with a suspected infection. Aside from routine infectious workup, at least three sets of blood cultures should be drawn within 24 hours with at least one culture from any indwelling central venous catheter. Any suspected source of infection should be swabbed or aspirated when clinically indicated (e.g., purulence from driveline infection, etc.). Inflammatory markers (such as erythrocyte sedimentation rate or serial C-reactive protein) should be considered. The ISHLT guidelines define the criteria for MCSD-specific infections and pocket infections [24].

Thrombosis, Thromboembolism, and Stroke

Based on clinical trials and postmarketing surveillance of the HM II, thrombosis rates of 2% to 4% have been reported [10,13,97]; however, a multicenter study noted an increased rate of pump thrombosis events of 8.4% at 3 months after implantation [98]. The risk of pump thrombosis was heralded by elevated lactate dehydrogenase levels, confirming its usefulness as a clinical biomarker. Pump thrombosis rates peaked at 1 month after implantation and began to decrease by 6 months. Treatment of pump thrombosis included heart transplantation, device replacement, medical therapy with anticoagulation augmentation, and/or thrombolytics. The morbidity and mortality of pump thrombosis was striking with a mortality of 48% among patients with device thrombosis who did not receive a heart transplantation or device replacement [98]. Based on multiple studies, the estimates of 1-year pump thrombosis incidence ranges between 6% to 12% for the HM II device and 5% to 13% for the HVAD [99]. Overall, one can conclude that the risk of thrombosis in the HM II has increased from levels seen during the 2008 to 2010 period, with the highest rates seen in 2013, and some evidence suggests that thrombosis risk may have declined in 2014 [100–102]. The exact cause of the increased rates of device thrombosis is currently unknown and is under active investigation.

Embolism may result from the pump as a result of inadequate anticoagulation, the cardiac chambers as a result of arrhythmias such as
atrial fibrillation, or may arise from the native vasculature as a result of the patients’ preexisting vascular atherosclerosis. The overall incidence of ischemic stroke varies greatly by type of device; however, with the current generation devices, the rate is 0.09 per patient-year overall and 0.05 per patient-year after 30 days [103]. The overall prevalence of ischemic cerebrovascular accidents (ICVA) and hemorrhagic cerebrovascular accidents (HCVA) in HVAD patients has been cited at 7% and 8%, respectively. Predictors of suffering an ICVA were the use of aspirin ≤81 mg and atrial fibrillation, whereas predictors of an HCVA were mean arterial pressure >90 mm Hg, aspirin ≤81 mg, and an INR >3.0. Likewise, sites that had established improved blood pressure management protocols demonstrated markedly lower rates of HCVA (1.8% vs. 10.8%) [104]. The strongest predictor of HCVA was an elevated mean arterial pressure, underscoring the importance of tight blood pressure management.

For patients who present with a new neurocognitive deficit, neurology consultation in conjunction with CT and angiography of the head and neck is recommended. An interrogation of device parameters to evaluate for signs of pump thrombosis or malfunction is warranted. A review of INR and lactate dehydrogenase trends should be done to look for patterns that would increase the risk of bleeding or thrombosis. In the setting of an HCVA, anticoagulation should be stopped and/or reversed.

Blood pressure management is critical to mitigate the risk of HCVA in this population, and guidelines advise a target mean arterial pressure of ≤80 mm Hg in all nonpulsatile VAD patients [24]. This is a level of evidence C recommendation and needs to be individualized to each patient based on their degree of pulsatility. Blood pressure measurement can be challenging because of the markedly low pulse pressure that is often encountered. Doppler probes are the current clinical standard to measure blood pressure, and the opening Doppler pressure has been shown to correlate with the systolic blood pressure of patients with significant pulsatility to allow discrimination between a systolic and mean blood pressure. In other words, the Doppler opening pressure closely approximates the mean arterial pressure for patients with low pulsatility.
Aside from the plethora of medical and surgical considerations, there are emotional, physical, and social considerations that require equal consideration. The acute nature of many patients’ illness often precludes a detailed assessment of such issues, but devoted addressal of these issues in nonemergent situations is vital to achieving both optimal outcomes, clinically and programatically. Physical limitations that may impact the patient’s ability to care for the device such as the manual dexterity to change batteries or auditory acuity to hear alarms are important and practical considerations. Adequate cognitive ability is needed to understand the importance of the device and its components, the ability to troubleshoot problems, and recognize when to ask for assistance. The emotional ability to adapt to the device, its implications, potential limitations, and adverse events is also important for maximizing long-term outcomes and quality of life. Finally, patients must have an adequate social support network; although having an implanted VAD does not typically involve constant supervision, there must be a background of reliable support for assistance in an emergency and for long-term emotional support.

In support of the above considerations, all patients should have a screen for psychosocial risk factors, cognitive dysfunction, and support structures prior to MCS. Routine cognitive testing may use a screening metric such as the Montreal Cognitive Assessment test \[105,106\]. If a history of psychiatric illness is present, a thorough evaluation by the psychiatry service should be performed to identify risk factors as well as initiate and/or optimize therapy. Medical compliance and coping capacity must also be assessed, given that poor compliance and coping are associated with adverse outcomes. If noncompliance has been demonstrated on repeated occasions, then, in most cases, MCS should not be offered \[24\].

Tobacco use is not an absolute contraindication for MCS; however, ongoing efforts should be made to counsel the importance of cessation. A timetable for tobacco cessation may be set a priori by individual programs. At least 6 months of tobacco cessation is required prior to cardiac transplantation. On the other hand, alcohol and substance abuse are strict contraindications to MCS. The timeline for abstinence can be determined by individual programs \[40\].
TIMING

When patients present to the intensive care unit with shock and are subsequently stabilized with aggressive medical therapy, the decision to transition to MCS rests on the expectation of improvement in the patient’s condition. Since 2008, the proportion of patients implanted in critical cardiogenic shock, INTERMACS Level 1, has remained stable at 15% [6]. The majority (65%) of patients are INTERMACS Level 2 (failing inotropes) or 3 (stable on inotropes), whereas 20% of patients have ambulatory, noninotrope-dependent HF (Levels 4 to 7) [6]. For those who received an intervention, such as revascularization, waiting to see the impact of this intervention on the patient’s clinical status is reasonable in the absence of further clinical deterioration. Many patients, however, will not have a readily identifiable or treatable proximate cause of their deterioration. For those who are eligible or are already listed for transplantation, the risk of continued medical therapy awaiting transplantation must be weighed against the risk of proceeding with MCS [107]. The advantages of waiting for transplantation in the setting of stable, yet critical illness are an increased likelihood of receiving an organ owing to a higher status, avoiding a second surgery, and bypassing the potential morbidity and mortality of MCS itself. Disadvantages to delaying MCS include the high-risk nature of transplantation during acute illness, further decompensation prior to transplantation that may require higher risk emergent univentricular or biventricular support, becoming too ill for either transplantation or mechanical support, or death. Proceeding with MCS early allows for surgery to be performed when the patient is less ill followed by a lower risk transplant once the patient is rehabilitated. Certain patients may be expected to have a short wait for transplantation based on their size, blood type, and level of sensitization, and the disadvantages of waiting for transplantation may be minimized. Others may have clear indications for early MCS such as persistent pulmonary hypertension not responsive to medical therapy [108]. Unfortunately, most patients do not have a clear delineation of risk, and determining the optimal timing of MCS can be quite difficult. There is an emerging consensus that earlier institution of mechanical support is preferable to waiting, because further decompensation will yield worse outcomes with both MCS and transplantation. For patients with multiorgan failure or on mechanical ventilation, strong consideration should be given to temporary MCS in order to optimize clinical status and assess long-term goals prior to placement of long-term MCS [24]. The ROADMAP (Risk Assessment and Comparative effectiveness of Left Ventricular Assist Device and Medical Management
in Ambulatory Heart Failure Patients) study examined the question of earlier implantation of DT LVAD in a less sick population of HF patients. The cohort was DT LVAD versus optimal medical therapy in NYHA functional class IIIB to IV chronic HF patients, not on inotropic therapy. Both showed a similar 20% mortality at 1 year. While the LVAD group had better functional capacity and quality of life, the group also experienced significantly more adverse events [109]. The optimal timing of device implantation remains controversial, but implanting patients who are INTERMACS profiles 6 and 7 likely results in no mortality benefit and a higher rate of adverse events.
FUTURE DIRECTIONS

MCS has evolved over the past 25 years from an investigational strategy reserved only for the moribund to a standard therapy supporting patients with stable advanced HF. Today, a wide variety of devices are available for short-, medium-, and long-term support at numerous centers worldwide.

A number of newer MCS devices are now in clinical use or clinical trials. The HeartWare Miniaturized Ventricular Asssist Device (MVAD) and the HeartMate 3 (Thoratec Corporation, Pleasanton, CA, USA) are both enrolling patients for multicenter, prospective trials titled the MVAD Advantage CE trial and The MOMENTUM 3 U.S. IDE Clinical trial, respectively (Fig. 197.6) [110,111]. The unique characteristics of the HeartWare MVAD include a magnetically suspended rotor that is housed within the inflow cannula as well as a wide-bladed design to minimize cellular trauma, while providing up to 10 L per minute of axial blood flow [112]. The HeartMate 3 LVAS provides magnetically levitated centrifugal flow with an artificial pulse mode allowing for enhanced pulsatility and an intended life span of at least 10 years [113]. Advances of pump technology are moving toward smaller pumps that still allow for full support, pumps that can be either implanted percutaneously or through minimally invasive surgeries, increased durability, totally implantable systems with transcutaneous energy transfer, and an improved device–patient interface. Research is also focused on improving biocompatibility, lowering risk of thrombosis, and better responsiveness to physiologic demands.
Medical Arm of Mechanically Assisted Circulatory Support (MedaMACS) is a medical arm of the INTERMACS database that was started in December 2012 with 154 patients enrolled, as of the Seventh INTERMACS report. It has enrolled INTERMACS Level 4 to 7 patients, and 1-year VAD/transplant-free survival has approached 75% [6]. MedaMACS will provide information about the risk of events among “stable” patients with advanced HF and offer guidance on the optimal timing of MCS therapy.
CONCLUSIONS

Einstein once quipped, “I never think of the future – it comes soon enough.” Though MCS was once considered to be science fiction, the reality of its place as an increasingly common HF therapy has arrived, and the future of its success depends on a continued commitment to further advances [114]. Though the field is still hindered by adverse events and technological limitations, those too are improving. Devices technology continues to evolve rapidly. Further desirable advances include freedom from an external drive line, as well as alternative energy sources, such as transcutaneous energy. As the number of patients with advanced HF increases, one can anticipate that the demand for and role of MCS, particularly DT, will expand significantly. Ideally, it is hoped MCS will be available to a greater proportion of patients with advanced HF, while resulting in continued improvement of outcomes and reduction of costs.

RENAL PROBLEMS IN THE INTENSIVE CARE UNIT

PANG-YEN FAN
NORMAL ACID–BASE PHYSIOLOGY

Acidemia and alkalemia denote, respectively, blood pH below or above the normal value of 7.40. A simple (single) acid–base disturbance always causes the blood pH to change. In comparison, the coexistence of two opposing primary acid–base disturbances, such as a metabolic acidosis as a result of diarrhea with metabolic alkalosis as a result of vomiting, may result in little or no deviation of the blood pH from normal. Maintenance of blood pH at approximately 7.40 is necessary to stabilize intracellular pH at 7.20, a crucial chemical condition for optimal cell physiology.

Renal Regulation of H⁺ Secretion

Maintenance of a normal plasma bicarbonate (HCO₃⁻) concentration depends on reclamation of the 4,500 mEq of HCO₃⁻ filtered by the kidneys each day. Reabsorption of filtered HCO₃⁻ takes place almost entirely in the proximal tubule (Fig. 198.1). In this process, luminal HCO₃⁻ combines with H⁺ secreted into the tubular lumen by a Na–H antiporter. The formation and subsequent dissociation of carbonic acid (H₂CO₃) to carbon dioxide (CO₂) and water (H₂O), catalyzed by carbonic anhydrase, permits CO₂ to enter the luminal membrane of the proximal tubular cell. Once inside the cell, CO₂ combines with OH⁻ to form HCO₃⁻. A Na-3HCO₃ cotransporter then carries HCO₃⁻ across the peritubular membrane into the blood. As a result, filtered HCO₃⁻ is returned to the
circulation without any net loss of $H^+$. 

![Figure 198.1](image)

**Figure 198.1** Proximal tubular reclamation of filtered bicarbonate ($HCO_3^-$). The first step in maintaining normal acid–base balance is the reabsorption of all filtered $HCO_3^-$. Inability to accomplish this results in metabolic acidosis (proximal, type 2, renal tubular acidosis) (see text for details). ATPase, adenosine triphosphatase.

A fall in proximal tubular bicarbonate reabsorption causes urinary $HCO_3^-$ losses and may lead to a fall in plasma $HCO_3^-$ concentration and to metabolic acidosis. The carbonic anhydrase inhibitor acetazolamide, for example, reduces the activity of luminal carbonic anhydrase, thereby decreasing the entry of $H_2O$ and $CO_2$ across the luminal membrane, which decreases $HCO_3^-$ reabsorption by the tubular cell (Fig. 198.1).

The process of reclamation for all filtered $HCO_3^-$ by itself is not sufficient to maintain a normal blood pH. The kidney must also excrete the 50 to 100 mEq per kg of $H^+$ generated each day from the metabolism of dietary proteins, particularly sulfur-containing amino acids (i.e., methionine, cysteine), which are converted to sulfuric acid. This acid load is initially buffered in the body to minimize changes in blood pH, causing a clinically undetectable decrease in the plasma $HCO_3^-$ concentration. The kidney must eventually excrete this daily acid increment to replete the $HCO_3^-$ used in this process or more severe acidemia will develop over
Energy requirements limit the ability of the kidney to excrete acid (H$^+$ ions) when the urine pH falls below 4.5. To offset this limitation, urinary buffers present in the urine maintain the urine pH above this critical value, permitting ongoing excretion of the daily acid load.

Two distinct urinary buffering systems enable continued H$^+$ secretion: titratable acids and ammonia. Titratable acids (primarily HPO$_4^{2-}$) are freely filtered through the glomerulus and can combine with H$^+$:

$$\text{HPO}_4^{-} + \text{H}^+ \rightarrow \text{H}_2\text{PO}_4$$

Titratable acidity is determined by adding alkali to the daily urine volume and equals the number of milliequivalents of base required to return the urine pH to 7.4. Approximately one-half of the daily acid load is excreted in this way.

By comparison, the most important urinary buffer is ammonia, because the abundance of this buffer can be varied according to physiologic needs. Ammonia synthesis occurs in the proximal tubule, derived principally from the breakdown of glutamine to α-ketoglutarate (Fig. 198.2). This process is stimulated by intracellular acidosis and by hypokalemia, both of which act by decreasing the intracellular pH (see the following discussion). Ammonia thus generated can combine with intracellular H$^+$, forming ammonium (NH$_4^+$). NH$_4^+$ is then secreted into the proximal tubule lumen by substituting for H$^+$ on the Na–H antiporter. Ammonia (NH$_3$) that forms by the dissociation of H$^+$ from NH$_4^+$ is largely reabsorbed, recycled, and then secreted into the collecting tubule. There, it is trapped in the tubular lumen as NH$_4^+$ by combining with secreted H$^+$ and excreted as ammonium chloride (NH$_4$Cl). For each molecule of buffered H$^+$ excreted in the urine, an HCO$_3^-$ is regenerated (Fig. 198.2), thus replenishing the HCO$_3^-$ used initially by the body to buffer daily metabolic acid load.
FIGURE 198.2 Excretion of the daily acid load permits the regeneration of bicarbonate (HCO₃⁻) that was used as a buffer. Two processes are involved: the excretion of titratable acid (A) and the excretion of ammonium (NH₄⁺) (B). The latter is particularly important because acidosis stimulates the breakdown of glutamine to ammonia. By comparison, hyperkalemia impairs the capacity of the proximal tubule to make ammonia, thus contributing to the metabolic acidosis observed in hyperkalemic disorders. ATPase, adenosine triphosphatase.
METABOLIC ACIDOSIS

Metabolic acidosis can be categorized by the presence or absence of an increased anion gap (AG). The anion gap (AG) refers to the difference between measured cations (Na\(^+\)) and measured anions (chloride [Cl\(^-\)] and HCO\(_3^-\)):

\[
AG = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)
\]

Potassium (K\(^+\)) is usually not included in the calculation of the AG because changes large enough to alter the gap significantly are uncommon or incompatible with life.

The normal AG varies between 3 and 11 mEq per L and averages approximately 7 to 8 mEq per L. These unmeasured anions consist of proteins (primarily albumin), sulfates, phosphates, and circulating organic acids. Uric acid is a large molecule and, therefore, does not contribute significantly to the AG even when hyperuricemia is present.

A reduction in the plasma albumin concentration can lower the baseline AG (approximately 2.5 mEq per L for every 1 g per dL fall in the albumin concentration) \[^1\]. Thus, the hypoalbuminemic patient may not have a high AG even in the presence of a disorder that typically causes an elevation (e.g., lactic acidosis; see later).

Metabolic Acidosis with an Increased Anion Gap

The causes of metabolic acidosis associated with an increased AG are listed in Table 198.1. Lactic acidosis is the most frequent form in hospitalized patients, whereas chronic renal failure is the principal cause of an increased AG for ambulatory persons.

Chronic Kidney Disease

Renal disease represents an interesting example of the potential overlap between normal and elevated AG acidosis. The high AG in patients with advanced chronic kidney disease is usually a late finding and reflects a severe reduction in glomerular filtration rate (GFR). As the GFR falls below 20 to 30 mL per minute (plasma creatinine >3 to 4 mg per dL), anions, such as sulfate and phosphate, that would normally be excreted by filtration are retained. With lesser degrees of renal dysfunction, however, metabolic acidosis appears primarily because H⁺ (HCl) secretion is reduced, with little or no effect on the AG.

The metabolically generated daily acid load on a typical American diet approximates 50 to 100 mEq. This acid, mainly sulfuric, is immediately buffered by NaHCO₃:

\[ \text{H}_2\text{SO}_4 + 2\text{NaHCO}_3 \rightarrow \text{Na}_2\text{SO}_4 + 2\text{CO}_2 + 2\text{H}_2\text{O} \]

The excess sulfate is excreted in the urine. If glomerular and tubular function decline in parallel, then the H⁺ and the SO₄²⁻ are retained, producing metabolic acidosis with a high AG. If, however, there is differential tubular dysfunction, the excretion of acid is diminished, but excretion of sulfate may be maintained owing to reduced reabsorption. In the latter setting, the AG may not rise as the serum HCO₃⁻ concentration decreases.

Therefore, the decrease in plasma HCO₃⁻ (severity of acidemia) need not correlate with extent of the rise in AG in renal dysfunction. Typically, the plasma bicarbonate concentration is greater than 12 mEq per L in patients with uncomplicated chronic kidney disease. A search for a second acid–base disorder is indicated when a lower HCO₃⁻ concentration is identified.

Lactic Acidosis

Lactic acidosis is the most common cause of severe metabolic acidosis
encountered in the intensive care unit. The AG is always increased above baseline (normal lactate level is <1.0 mmol per L) because lactate does not appear in the urine until a higher plasma concentration (at least 6 to 8 mmol per L) is achieved. Lactate levels greater than 5 mmol per L are considered diagnostic of lactic acidosis, although levels between 2 and 5 mmol per L may be significant in the appropriate clinical circumstances. Metformin, a biguanide commonly used in the treatment of type II diabetes mellitus, can cause lactic acidosis, particularly in patients who present with acute or chronic renal insufficiency. Hemodialysis has been used in the treatment of metformin-induced acidosis [2].

Most cases of lactic acidosis involve the L-isomer. By comparison, D-lactic acidosis, a disorder observed most commonly in patients with short bowel syndrome, results in a rise in the AG, but the lactate level is normal [3]. D-Lactate, generated by intestinal bacteria, is not detected by the usual lactate assay, and a specific enzymatic assay must be requested to diagnose this disorder.

**Ketoacidosis**

Ketoacidosis occurs when acetoacetic acid and β-hydroxybutyric acid are overproduced by the liver (for a complete discussion, see Chapter 137). Acetone, a breakdown product of acetoacetic acid, is not an acid and does not contribute to the acidemia or to the increased AG observed in this disorder.

Although ketoacidosis is generally associated with an elevated AG, loss of ketoanions in the urine, particularly during intravenous fluid therapy, may attenuate the expansion of the AG. Once formed, ketones may be excreted in the urine before, under the influence of insulin, they can be metabolized back to HCO$_3^-$ . Because ketoacids titrate the plasma HCO$_3^-$ concentration downward, the loss of urinary ketoanions (as sodium or potassium salts) is tantamount to the renal loss of HCO$_3^-$ . Thus, a high AG metabolic acidosis is often present before therapy in individuals with ketoacidosis, but may convert to a normal AG metabolic acidosis with saline repletion and cessation of ketogenesis. Sodium-glucose cotransporter-2 inhibitors, used in the treatment of type 2 diabetes, may increase the risk of ketoacidosis.

**Rhabdomyolysis**

Massive muscle breakdown is an important cause of metabolic acidosis with an increased AG. Acute kidney injury as a result of myoglobinuria can cause retention of anions (e.g., phosphate) that have been released from damaged myocytes.
Ingestions

The most common acid–base abnormality observed with salicylate intoxication is a respiratory alkalosis caused by direct stimulation of the medullary respiratory center. With moderate-to-severe salicylate intoxication, the AG increases as salicylic acid promotes formation of lactic acid, rather than accumulation of salicylate in the blood. The consequence is a mixed respiratory alkalosis with a high AG metabolic acidosis.

Methanol and ethylene glycol ingestions require early diagnosis because prompt treatment may be lifesaving. Inhibitors of alcohol dehydrogenase such as ethanol and fomepizole can limit the conversion of the alcohols to their more toxic metabolic products, with fomepizole being the preferred agent. The clinical features of these ingestions are discussed in detail in Chapter 119.

Detection of an osmolal gap suggests methanol or ethylene glycol poisoning and may avoid delayed treatment while awaiting lab measurement of these toxins. The osmolal gap refers to the difference between the plasma osmolality ($P_{\text{Osm}}$) measured by the laboratory and that calculated using the following formula:

$$\text{Calculated } P_{\text{Osm}} (\text{mOsm/kg}) = (2 \times \text{Na}^+) + (\text{glucose}/18) + (\text{BUN}/2.8) + (\text{ethanol}/3.7)$$

Normally, the measured $P_{\text{Osm}}$ is higher than the calculated value by 10 mOsm per kg. A larger osmolal gap indicates the presence of osmotically active substances not normally present. The most frequent causes of an increased osmolal gap are ethyl alcohol, isopropyl alcohol, ketones, lactate, mannitol, ethylene glycol, and methanol. If ethanol, lactate, or ketones cannot be identified in a patient with an AG metabolic acidosis with an osmolal gap, the diagnosis of ethylene glycol or methanol intoxication should be strongly suspected. In the intensive care unit setting, a high osmolal gap acidosis has also been associated with the use of continuous high-dose intravenous infusions of lorazepam for more than 48 hours. Propylene glycol, which is used as a solvent for intravenous medications including lorazepam, has been implicated as the cause of the hyperosmolar metabolic acidosis in this scenario [5]. It is important to understand that the presence of an osmolal gap that results from an ingested alcohol may only be detected when $P_{\text{Osm}}$ is measured in the laboratory by freezing-point depression [6]. In addition, after the alcohol is metabolized, the osmolal gap may disappear.
Toluene (present in glue and metabolized to hippuric acid) is a rare cause of metabolic acidosis. The AG rises early and then returns toward normal, because hippurate is excreted by the kidneys, a process that is similar to the renal handling of ketones (see previous discussion).

Rarely, acetaminophen administration in therapeutic doses can lead to an elevated AG metabolic acidosis in metabolically stressed individuals, including pregnant women. In this setting, reduced glutathione stores permit the generation of pyroglutamic acid (5-oxoproline) [7].

**Metabolic Acidosis with a Normal Anion Gap**

Metabolic acidosis with a normal AG, which may also be called a *hyperchloremic acidosis*, is associated with the conditions listed in Table 198.2. The decrement in the plasma HCO$_3^-$ concentration is matched by a rise in the plasma Cl$^-$ level, maintaining electroneutrality.

**Acid and Chloride Administration**

The infusion of amino acid solutions during hyperalimentation is an abundant source of hydrochloric acid (HCl). The development of a metabolic acidosis is more common in patients with renal insufficiency. Oral administration of cholestyramine chloride reportedly occasionally also causes acidemia. This resin, which is sometimes used in the management of hypercholesterolemia, is nonresorbable and can act as an anion-exchange resin, exchanging its Cl$^-$ for endogenous HCO$_3^-$ and producing a metabolic acidosis. Sevelamer hydrochloride, a compound used as a phosphorous binder in chronic kidney disease, has been associated with lower bicarbonate levels than in those patients treated with calcium-based binders. The mechanism of the metabolic acidosis is believed to be similar to cholestyramine [8].

**Bicarbonate Losses**

Loss of HCO$_3^-$ from the gastrointestinal tract or kidneys can lead to a reduction in the plasma HCO$_3^-$ level. Bowel contents are alkaline compared to blood because HCO$_3^-$ is added by pancreatic and biliary secretions. Most of the secreted alkali is reclaimed by as HCO$_3^-$ is exchanged for Cl$^-$ in the ileum and colon. Gastrointestinal losses of HCO$_3^-$ are most commonly observed in patients with diarrhea so severe that colonic transit time is too rapid for alkali reabsorption. At times, the
resulting $\text{HCO}_3^-$ losses can approach 40 mEq per L of stool. Less frequently, metabolic acidosis from $\text{HCO}_3^-$ depletion is a result of pancreatic fistulae, biliary drainage, or a ureterosigmoidostomy. In the last circumstance, the excretion of acid (as $\text{NH}_4\text{Cl}$) urine directly into the colon permits the exchange of $\text{HCl}$ for $\text{HCO}_3^-$ because the colon is permeable to $\text{H}^+$ and $\text{Cl}^-$, unlike the urinary bladder. This problem does not usually occur with an ileal bladder.

Pancreatic $\text{HCO}_3^-$ losses are also observed in essentially all patients with a pancreatic allograft anastomosed directly to the urinary bladder. Bicarbonate secreted into the bladder cannot be reabsorbed.

Renal tubular acidosis (RTA) can be classified as type 1 (distal), type 2 (proximal), and type 4 (hypoaldosteronism). Type 3 refers to what is now considered to be an infantile variant of type 1; therefore, type 3 RTA is a term not generally applied to adults. Renal bicarbonate losses can cause or contribute to acidemia in type 2 (proximal) RTA (Table 198.2), during recovery from ketoacidosis (see previous discussion), and for patients who are posthypocapnia. For patients with proximal RTA (Table 198.3), the normal reabsorptive threshold for $\text{HCO}_3^-$ is reduced. As a result, $\text{HCO}_3^-$ can no longer be reabsorbed at a rate adequate to maintain the normal plasma level of approximately 25 mEq per L. As a consequence, the urine pH is initially alkaline (>5.3), and the fractional excretion of $\text{HCO}_3^-$ is elevated (>15% of the filtered load, with normal <3%). However, $\text{HCO}_3^-$ wasting ceases, and the urine becomes acidic (pH <5.3) once the plasma $\text{HCO}_3^-$ concentration drops below the new (lower) $\text{HCO}_3^-$ reabsorptive threshold. This process explains why the urine pH may be high or low in proximal RTA.

RTA, renal tubular acidosis.

Renal $\text{HCO}_3^-$ losses also occur as compensation for chronic respiratory alkalosis (chronic hypocapnia). During chronic hyperventilation, the blood pH increases as the $\text{PCO}_2$ decreases. As can be seen in Figure 198.1, an increase in intracellular pH diminishes $\text{H}^+$ excretion, thereby leading to a concomitant decrease in $\text{HCO}_3^-$ reabsorption. These changes cause the plasma $\text{HCO}_3^-$ concentration to fall, partially compensating for the alkalemia. If the stimulus for hyperventilation (e.g., hypoxemia) is suddenly eliminated, the $\text{PCO}_2$ rapidly returns to normal. Renal compensation, by comparison, continues for 1 to 2 more days, causing a persistent reduction in the plasma $\text{HCO}_3^-$ concentration. The resulting posthypocapnic metabolic acidosis normally resolves spontaneously.

**Reduced Renal $\text{H}^+$ Excretion**

Reduced renal acid excretion can be observed in four conditions: chronic kidney disease, type 1 (distal) RTA (Table 198.3), type 4 RTA (hypoaldosteronism), and states of reduced renal perfusion. The acidosis of chronic kidney disease is primarily caused by a reduction in ammonia production. Patients with chronic renal insufficiency have a substantial decline in the number of functioning nephrons. Nephrons that continue to filter, however, characteristically have filtration rates and acid excretion rates per nephron that are above normal. Impaired acid excretion in these patients occurs because the number of hyperfiltering nephrons is inadequate to compensate for those that are nonfunctioning.
The AG is frequently normal in mild-to-moderate kidney disease (plasma creatinine < 3 mg per dL) because Cl− replaces the HCO₃− used to buffer the retained acid. At this time, the GFR is still high enough to permit the excretion of anions like phosphate, which contribute to the rise in AG as renal function declines further.

The classic form of type 1 (distal) RTA (Table 198.3) occurs when H⁺ cannot be pumped into the tubule lumen by the intercalated cells of the collecting tubules. The result is that urine cannot be maximally acidified (urine pH is always ≥5.5). In addition to metabolic acidosis, hypokalemia is typically present. The K⁺ deficit is caused, in part, by enhanced distal nephron Na−K exchange, a process that is necessary to maintain Na⁺ balance because H⁺ cannot be secreted in response to Na⁺ reabsorption. Distal RTA may also result from a translocation of the bicarbonate–chloride exchanger from the peritubular to the luminal membrane, leading to secretion of bicarbonate into the collecting tubule lumen.

The most important clinical complication of distal RTA is the formation and deposition of calcium throughout the kidney (nephrocalcinosis). This process begins in the collecting tubules, where the urine is most concentrated, and is commonly accompanied by the formation of calcium phosphate calculi. The factors that may contribute to the renal stone disease in this disorder include hypercalciuria, because metabolic acidosis causes a release of bone calcium that can then be filtered and excreted; the alkaline urine pH, which predisposes to the precipitation of calcium phosphate crystals; and, most importantly, hypocitraturia. The reduction in urinary citrate is a direct result of the metabolic acidosis, which increases proximal tubular citrate reabsorption. Because calcium citrate is significantly more soluble than calcium phosphate, hypocitraturia facilitates the precipitation of calcium phosphate crystals in the tubular lumen. In comparison with distal RTA, stone formation is less common and less severe in patients with proximal RTA, possibly because a proportion of these patients may have the full Fanconi’s syndrome, in which proximal tubular reabsorption of HCO₃⁻ and many other substances, including citrate, is impaired [9].

In addition to the classic form of type 1 (distal) RTA, in which hypokalemia is characteristic, a hyperkalemic variety has also been described. This disorder, as well as type 4 (hypoaldosteronism) RTA, is discussed in Chapter 199.
Clinical Signs and Symptoms of Metabolic Acidosis

Kussmaul’s respirations on physical examination suggest the presence of metabolic acidosis. This unusual respiratory pattern reflects an increase in tidal volume rather than a rise in respiratory rate and is caused by stimulation of the respiratory center in the brainstem by the low blood pH. As acidemia becomes more severe, nausea and vomiting or mental status changes, including coma, may occur.

Secondary hypotension also may be observed in severely acidemic patients, the hypotension resulting from depressed myocardial contractility and arterial vasodilation. Although circulating catecholamines may initially counteract the adverse cardiovascular effects of acidemia, such compensation becomes insufficient as the blood pH falls below 7.20.

The plasma K\(^+\) concentration may be altered by the degree of metabolic acidosis. Infusion of a mineral acid such as arginine HCl, for example, causes a prompt rise in the plasma K\(^+\) concentration as K\(^+\) moves out of cells in exchange for H\(^+\). By comparison, a shift of K\(^+\) is less likely to occur in those patients with metabolic acidosis caused by organic acids, such as lactic and ketoacidosis. The reason for this apparent difference is uncertain, but it may relate to the release of insulin by organic substrates (e.g., lactate), which would drive K\(^+\) into cells.

Diagnosis

Metabolic acidosis is easily diagnosed by the presence of a low blood pH and plasma bicarbonate concentration. The detection of a widened AG can then be used to identify a specific cause for the disorder. The likelihood of identifying a specific acid(s) in a patient with a high AG acidosis increases as the width of the AG increases.

While patients may have a simple metabolic acidosis, many individuals have a concomitant respiratory or second metabolic acid–base disorder. To distinguish mixed from simple acid–base disorders, knowledge of the appropriate respiratory compensation as well as an understanding of the ratio of the increment in AG to decrement in plasma HCO\(_3^-\) concentration is useful.

Respiratory Compensation

Stimulation of the brainstem respiratory center by acidemia causes a fall in the PCO\(_2\). In uncomplicated metabolic acidosis, the PCO\(_2\) is expected to fall by 1.2 mm Hg for each 1 mEq per L decrease in the HCO\(_3^-\).
Alternatively, the PCO\textsubscript{2} can be estimated from the following equation:

\[
\text{Expected PCO}_2 (\text{mm Hg}) = [(1.5 \times \text{HCO}_3^-) + 8] \pm 2
\]

A PCO\textsubscript{2} that is substantially different from the expected value indicates a superimposed respiratory acidosis or alkalosis. For example, if the plasma bicarbonate concentration was 10 mEq per L, the expected PCO\textsubscript{2} would be approximately 23 mm Hg \([(1.5 \times 10) + 8 = 23]\). A lower PCO\textsubscript{2} would indicate the presence of a concomitant respiratory alkalosis (as might be seen with a salicylate overdose), whereas a higher PCO\textsubscript{2} would signify a simultaneous respiratory acidosis. \textit{This calculation is useful only in the evaluation of the respiratory response to metabolic acidosis and it is inaccurate when the plasma bicarbonate concentration is more than 20 mEq per L.}

By a quirk of mathematics, the last two digits of the pH equal the PCO\textsubscript{2} in moderate metabolic acidosis if respiratory compensation is appropriate. For example, the PCO\textsubscript{2} in a patient with a pH of 7.27 should be 27 mm Hg. A lower PCO\textsubscript{2} indicates a superimposed respiratory alkalosis, whereas a higher value signifies a primary respiratory acidosis. This approach is invalid for severe acidosis with pH approaching or below 7.00, given the limitations of respiratory compensation.

**Change in Anion Gap to Change in Bicarbonate Concentration Ratio**

In patients with a high AG metabolic acidosis, the identification of a second metabolic acid–base disorder (normal AG acidosis) can be made by comparing the change in the AG to the change in the plasma HCO\textsubscript{3}− concentration.

The elevation in AG is because of the increase in the unmeasured anions. However, there is not always a one-to-one relationship between the increase in AG (\(\Delta\text{AG}\)) and the fall in plasma bicarbonate (\(\Delta\text{HCO}_3^-\)) because some of the excess hydrogen ions are buffered by nonbicarbonate buffers (including intracellular proteins and bone) and the \(\Delta\text{AG}\), therefore, generally exceeds \(\Delta\text{HCO}_3^-\). In lactic acidosis, the \(\Delta\text{AG}/\Delta\text{HCO}_3^-\) ratio averages approximately 1.4 to 1.6:1. In contrast, the \(\Delta\text{AG}/\Delta\text{HCO}_3^-\) ratio averages approximately 1:1 in ketoacidosis caused by the loss of ketoacid anions in the urine which lowers the elevated AG without affecting the plasma HCO\textsubscript{3}− concentration. Patients with relatively
normal renal function can lose large quantities of ketoacids in the urine and may have a $\Delta \text{AG}/\Delta \text{HCO}_3^-$ ratio below 1. In fact, the loss of ketoacid anions in the urine causes the frequent development of a hyperchloremic (normal AG) metabolic acidosis during the treatment (recovery phase) of diabetic ketoacidosis. In contrast, urinary anion loss is minimal in lactic acidosis because shock is typically associated with reduced urinary flow rate, and most of the lactate that is filtered can be reabsorbed by a specific sodium-$L$-lactate cotransporter in the luminal membrane of the proximal tubular cells. Thus, when the $\Delta \text{AG}$ is more than double the $\Delta \text{HCO}_3^-$, a coexisting metabolic alkalosis and metabolic acidosis is likely. An example of this situation would be severe vomiting in a patient with ketoacidosis. A $\Delta \text{AG}$ less than the $\Delta \text{HCO}_3^-$ suggests concomitant high AG and normal AG metabolic acidosis as could occur in a patient with bicarbonate losses from diarrhea combined with lactic acidosis from hypotension.

Changes in the concentration of other unmeasured cations or anions in the plasma can also lead to miscalculation of the AG. As an example, hypoalbuminemia (decreased unmeasured anions) and severe hypercalcemia (increased unmeasured cations) can lower the AG. Thus, a patient with one or both of these disorders may have a baseline AG of 4 rather than 8 or 9 mEq per L. As a result, calculation of the $\Delta \text{AG}/\Delta \text{HCO}_3^-$ ratio is most accurate when the preacidosis AG is known.

---

**Urinary Anion Gap**

Another useful tool in the evaluation of a metabolic acidosis is the urinary AG (UAG). UAG is the difference between the sum of the urinary $\text{Na}^+$ and $\text{K}^+$ and the urinary $\text{Cl}^-$:

$$UAG = (\text{Na}^+ + \text{K}^+) - \text{Cl}^-$$

The most frequent use of the UAG is to identify the etiology of a normal AG metabolic acidosis with hypokalemia. The most common nonrenal cause is diarrhea, which provokes an appropriate increase in renal $\text{H}^+$ secretion. These additional $\text{H}^+$ ions are buffered in the urine by ammonia and excreted primarily as $\text{NH}_4\text{Cl}$. Because $\text{NH}_4^+$ is not measured in the calculation of the UAG, but $\text{Cl}^-$ is, an increased rate of renal $\text{H}^+$ secretion causes the UAG to become a negative number. Conversely, the presence
of a positive UAG in an individual with a non-AG metabolic acidosis suggests that the disorder is caused by impaired renal H⁺ excretion (e.g., distal RTA). In this setting, impaired H⁺ secretion leads to a fall in urinary Cl⁻ (which would be excreted as NH₄Cl) and a positive calculated UAG. It is important to note, however, that underlying renal insufficiency may also be associated with impaired NH₄Cl excretion owing to a limitation in ammonia synthesis; in these individuals, the UAG may remain positive even in the presence of diarrhea.

**Treatment of Metabolic Acidosis**

Treatment of metabolic acidosis must be directed at correction of acidemia as well as the cause of the acid–base disturbance. The likelihood that alkali administration is necessary and that it will be effective depends on the blood pH, compensatory mechanisms, and the underlying cause.

The degree of acidemia and hypobicarbonatemia should be evaluated before administering alkali. As a general rule, alkali therapy generally is not needed until the arterial blood pH drops below 7.15 to 7.20. An exception may occur when the plasma HCO₃⁻ concentration falls to less than 10 to 12 mEq per L, despite a blood pH of more than 7.15. Alkali administration is usually unnecessary if the acidosis is likely to resolve spontaneously (e.g., lactic acidosis after a grand mal seizure).

**Alkali Administration**

HCO₃⁻ therapy should be considered in patients with moderate-to-severe metabolic acidosis. However, depending on the etiology, the use of exogenous bicarbonate remains controversial. The initial goal of alkali therapy is to raise the arterial blood pH to 7.20, a typically safe level at which the patient is at less risk of cardiovascular compromise. The pH does not need to be corrected back to normal because the potential risks of HCO₃⁻ therapy (e.g., hypernatremia, hypercapnia, fluid overload, cerebrospinal fluid acidosis, and “overshoot” alkalosis) are likely to outweigh the benefits, as long as renal function (and therefore acid-excretory ability) is relatively intact.

The quantity of exogenous bicarbonate required to produce a change in pH is determined by estimating the total body HCO₃⁻ deficit. The apparent HCO₃⁻ space is about 50% of lean body weight in healthy subjects. In patients with more severe metabolic acidosis (plasma HCO₃⁻
concentration <10 mEq per L), cellular and bone buffering become more prominent owing to the marked reduction in the quantity of available extracellular buffer (primarily HCO$_3^-$). This preferential entry of H$^+$ into cells causes the HCO$_3^-$ space to expand to approximately 70% of the lean body weight. The volume of distribution for bicarbonate (bicarbonate space) can be estimated by the following equation:

$$\text{Bicarbonate space} = (0.4 + \frac{2.6}{[\text{HCO}_3^-]}) \times \text{lean body weight (in kg)}$$

These are only rough guidelines and cannot replace ongoing monitoring of serum bicarbonate level and arterial pH during the correction phase. Furthermore, if there is continuing alkali loss from diarrhea, then the HCO$_3^-$ requirements are substantially increased because the apparent volume of distribution of HCO$_3^-$ is much greater than 70% of body weight in this setting.

**Treatment of Specific Causes of Metabolic Acidosis**

**Renal Disease.** Treatment of the metabolic acidosis of renal dysfunction depends on the clinical manifestations and the severity of the acidosis. Most individuals with acute kidney injury can be managed with dialysis or using the guidelines for alkali administration listed previously. There is some recent data suggesting that alkali therapy can slow down the rate of decline in chronic kidney disease and reduce mortality in this setting [10].

**Ketoacidosis.** While correction of volume depletion is an essential part of initial management of patients with diabetic ketoacidosis, the utility of intensive fluid administration may be limited after the intravascular volume has been restored because volume expansion then leads to the excretion of ketone anions in the urine. Moreover, excessive expansion of the plasma volume reduces proximal tubular HCO$_3^-$ reabsorption, in part, by reducing Na–H exchange. The net effect is normalization of the AG without a significant increase in the plasma HCO$_3^-$ concentration. In this setting, spontaneous correction of the metabolic acidosis requires regeneration of new bicarbonate by the kidney (a process that may take several days), in contrast to the rapid increase in HCO$_3^-$ that occurs when ketone anions are metabolized back to HCO$_3^-$ in the liver as insulin is given. Consequently, fluid administration should be tempered after intravascular volume compromise has been corrected.

Alkali administration is not usually necessary for patients with
ketoacidosis. There appears to be no difference in mortality between patients treated with NaHCO₃ and controls [11]. Insulin therapy should raise the plasma HCO₃⁻ concentration because ketone anions are metabolized. Patients who may benefit from cautious alkali therapy include those with severe acidemia and cardiovascular compromise and those with a normal AG acidosis. As already discussed, the latter condition pertains to those who have sustained major urinary losses of ketones, rendering them depleted of potential bicarbonate substrate.

**Lactic Acidosis.** Correction of any predisposing disorder is the primary therapy for lactic acidosis. Reversal of circulatory failure, hypoxemia, or sepsis reduces the rate of lactate production and enhances its removal.

The benefit of NaHCO₃ in the treatment of lactic acidosis remains unproven [11]. The potential benefits of alkali administration principally involve the maintenance of normal cardiovascular homeostasis through correction of acidosis. This potential advantage must be weighed against possible deleterious effects, such as volume overload, hypernatremia, and overshoot alkalosis, after restoration of tissue perfusion. As a result of these potential problems, no concrete recommendations can be made regarding alkali therapy in lactic acidosis. One approach might be to administer HCO₃⁻ to maintain the arterial blood pH above 7.15 to 7.20 and the plasma HCO₃⁻ concentration above 10 to 12 mEq per L, as suggested previously (see “Alkali Administration” section). However, if the lactate level increases without a significant improvement in clinical status or blood pH, the benefit of continuing alkali administration should be questioned. It appears that correction of the underlying cause of lactic acidosis is the most important goal, because measures to raise the bicarbonate level without a fall in lactate have not been associated with a reduction in mortality. These findings are consistent with the hypothesis that the high mortality in lactic acidosis results from the underlying disorder causing the acidosis, but not from the acidemia per se.

**Drug and Toxin Ingestions.** The treatment of toxins and ingestions is discussed in Section on Pharmacology, Overdoses, and Poisonings.

**Renal Tubular Acidosis.** The acidemia of type 1 (distal) RTA can be corrected with HCO₃⁻ or a precursor such as citrate. The usual requirement is 1 to 3 mEq/kg/d, which should be sufficient to buffer that fraction of the daily acid load (50 to 100 mEq per day) that is not being
excreted. In general, a potassium salt is administered (e.g., potassium citrate) because this repairs the K⁺ deficit as well. Large doses of oral NaHCO₃ can cause gastrointestinal symptoms by generating CO₂ in the stomach. This problem can be minimized by the use of citrate, most of which is ultimately metabolized in the body to HCO₃⁻. Solutions are available that contain 1 to 2 mEq per mL of sodium, potassium, or sodium and potassium citrate.

The initial step in the management of type 2 (proximal) RTA is to determine the presence of a treatable underlying disorder, such as vitamin D deficiency, multiple myeloma, or the use of a carbonic anhydrase inhibitor. Even if no specific therapy is available, correction of the acidemia may not be required in adults if the patient is asymptomatic and if there is only mild-to-moderate reduction in the plasma HCO₃⁻ concentration. In comparison, treatment is always indicated in young children because restoring acid–base balance can permit normal growth to resume.

The evaluation and treatment of the hyperkalemic form of distal RTA and of type 4 RTA (hypoaldosteronism), in which hyperkalemia is also present, can be found in Chapter 199.
METABOLIC ALKALOSIS

Primary metabolic alkalosis is characterized by an elevated plasma HCO$_3^-$ concentration in the presence of an arterial pH above 7.40. Hyperbicarbonatemia may represent an appropriate response to chronic respiratory acidosis, which can be easily diagnosed by measurement of the arterial blood pH.

Pathophysiology and Etiology

There are two steps involved in the development of metabolic alkalosis. The factors that generate alkalosis may differ from those that maintain it. A primary rise in the plasma HCO$_3^-$ concentration can be induced by several mechanisms: (a) loss of acid from the gastrointestinal tract or in the urine, (b) administration of HCO$_3^-$ or a precursor such as citrate, or (c) loss of fluid with a Cl$^-$ to HCO$_3^-$ ratio that is higher than that of plasma. The third condition is sometimes referred to as contraction alkalosis because the total HCO$_3^-$ content remains relatively unchanged while the extracellular fluid volume “contracts around it,” thereby elevating the HCO$_3^-$ concentration. In contrast to the first two mechanisms, contraction alkalosis is rarely responsible for more than a mild increase in the plasma HCO$_3^-$ concentration. Loss of fluid with an electrolyte composition similar to that of plasma, as might occur with hemorrhage, does not result in a contraction alkalosis because HCO$_3^-$ is lost proportionately to the other molecular components of plasma.

The excess in HCO$_3^-$ generated by any of these processes should be rapidly excreted in the urine. The maintenance of a metabolic alkalosis, therefore, indicates an impairment of renal HCO$_3^-$ excretion. The most common hindrances to renal disposal of bicarbonate are volume and potassium depletion.

Under ordinary conditions, HCO$_3^-$ appears in the urine when the plasma level rises above the normal value of approximately 25 mEq per L. In the presence of volume depletion, however, the capacity of the proximal tubule to reabsorb HCO$_3^-$ increases, allowing the plasma HCO$_3^-$ level to rise without triggering bicarbonaturia. Several mechanisms account for these changes, including stimulation of luminal
Na–H countertransport (Fig. 198.1) by angiotensin II, generated in response to volume contraction. Most hypovolemic states are associated with Cl− depletion. Because tubular luminal Cl− appears to be important in distal nephron Cl−–HCO3− exchange, it is not surprising that correction of the metabolic alkalosis usually requires Cl− repletion as well. In comparison, giving Cl− may be ineffective when primary or secondary hyperaldosteronism, severe hypokalemia, or renal insufficiency is responsible for the defect in HCO3− excretion. The cause of a metabolic alkalosis can usually be identified by how readily it responds to administration of Cl− (see “Diagnosis” section). The effect of hypokalemia in the maintenance of metabolic alkalosis is discussed later in this chapter.

**Alkali Administration**

Because administered HCO3− is normally excreted rapidly in the urine, alkali administration must be massive, or renal impairment must limit the excretion of HCO3− if metabolic alkalosis is to develop. Milk-alkali syndrome is an uncommon disorder characterized by hypercalcemia and metabolic alkalosis. The chronic ingestion of milk and calcium carbonate–containing antacids can lead to the development of metabolic alkalosis when the increased HCO3− load cannot be excreted as a result of renal impairment from chronic hypercalcemia. This condition is now rarely seen, probably because nonabsorbable antacids, proton-pump inhibitors, and H2-blockers have largely supplanted the use of large quantities of baking soda and milk as treatment of gastritis and peptic ulcer disease.

**Chloride-Responsive Metabolic Alkalosis**

**Generation of Chloride-Responsive Metabolic Alkalosis.** The two most common causes of metabolic alkalosis are diuretic therapy and loss of gastric secretions (resulting from nasogastric suction or vomiting) (Table 198.4). Thiazide and loop diuretics can induce H+ loss from increased distal Na+ presentation in the presence of elevated aldosterone levels, which causes enhanced distal nephron Na–H exchange. Hydrogen secretion in this nephron segment is associated with increased HCO3− generation. The proximal tubule may also play an important role because stimulation of the renin–angiotensin system by volume depletion
enhances the activity of the Na–H antiporter, thereby increasing H⁺ secretion and HCO₃⁻ reabsorption. To the degree that the urinary anion losses represent primarily Cl⁻, a component of contraction alkalosis may also occur.

*a* Most common causes.

*b* Primary hyperparathyroidism is frequently associated with a mild metabolic acidosis (see text for details).

Although volume contraction may contribute to the metabolic alkalosis caused by vomiting and nasogastric suction, and occasionally with
intestinal Cl− wasting, gastric H+ losses are primarily responsible for the generation of metabolic alkalosis in this setting. Secretion of gastric acid results in the retention of 1 mEq of HCO₃⁻ for each milliequivalent of H⁺ that is secreted because both of the ions are derived from the intracellular dissociation of carbonic acid:

$$H_2CO_3 \rightarrow HCO_3^- + H^+$$

This process does not normally lead to metabolic alkalosis because the 80 to 200 mEq of HCl secreted by the stomach each day enters the duodenum, where it stimulates an equivalent amount of HCO₃⁻ secretion from the pancreas. By comparison, when vomiting or nasogastric suctioning occurs, the H⁺ secreted by the stomach never reaches the duodenum and, therefore, cannot induce pancreatic HCO₃⁻ secretion. Hence, there is a net retention of HCO₃⁻. As in diuretic use, distal nephron Na−H exchange also contributes to the development of this disorder because aldosterone levels are stimulated by the loss of extracellular volume.

Metabolic alkalosis may also be observed after the rapid correction of chronic respiratory acidosis. This posthypercapnic metabolic alkalosis occurs because chronic respiratory acidosis activates compensatory renal mechanisms that induce HCl loss in the urine; the ensuing rise in the plasma HCO₃⁻ concentration is appropriate in that it returns the arterial pH toward normal. The plasma HCO₃⁻ generally increases by approximately 3.5 mEq per L for every 10 mm Hg rise in the arterial PCO₂. If hypercapnia is rapidly reversed, however (most frequently by artificial ventilation), the excess HCO₃⁻ that has been generated may persist, and alkalemia ensues.

**Maintenance of Chloride-Responsive Metabolic Alkalosis.** As reviewed previously, renal excretion of HCO₃⁻ normally begins when the plasma level exceeds 25 mEq per L. The normal kidney can excrete large quantities (>1,000 mEq per L) without a substantial increase in the plasma HCO₃⁻ concentration. As a result, maintenance of a Cl⁻-responsive alkalosis implies a reduction in renal HCO₃⁻ excretion.
Reduced GFR and, more importantly, enhanced proximal tubular NaHCO$_3$ reabsorption limit HCO$_3^-$ excretion, allowing the increase in plasma HCO$_3^-$ to persist. Normally, Cl$^-$ is the major anion reabsorbed with Na$^+$. In states of Cl$^-$ depletion, as occurs in Cl$^-$-responsive metabolic alkalosis, however, Na$^+$ must be reabsorbed with the next most abundant anion, HCO$_3^-$. Consequently, the need to preserve volume prevents correction of the alkalosis.

Hypokalemia also promotes renal HCO$_3^-$ reabsorption and contributes to the maintenance of metabolic alkalosis. K$^+$ losses frequently occur with diuretic administration or gastric acid losses. If the plasma HCO$_3^-$ concentration exceeds the reabsorptive capacity of the proximal renal tubule, the resultant bicarbonaturia obligates excretion of a cation (e.g., Na$^+$). Some of the Na$^+$ leaving the proximal tubule with HCO$_3^-$ is then reabsorbed distally in exchange for K$^+$. These urinary K$^+$ losses are primarily responsible for the hypokalemia seen with vomiting; gastric K$^+$ losses are usually less important because these secretions have a K$^+$ concentration of less than 10 mEq per L. As a result of K$^+$ depletion, relative intracellular acidosis occurs as H$^+$ shifts into cells to maintain electroneutrality as K$^+$ moves extracellularly in response to hypokalemia. Ultimately, this intracellular acidosis stimulates proximal tubular Na–H exchange, which further reduces renal HCO$_3^-$ excretion (Fig. 198.1).

**Chloride-Resistant Metabolic Alkalosis**

Metabolic alkalosis in some individuals is not responsive to the administration of Cl$^-$-containing solutions. In these disorders, a primary increase in mineralocorticoid activity, potassium depletion, or disorders of renal tubular Cl$^-$ wasting (Bartter’s and Gitelman’s syndromes) are usually responsible for the generation and maintenance of the alkalosis. In all of these circumstances, there is enhanced renal H$^+$ excretion and HCO$_3^-$ reabsorption. Either there is no Cl$^-$ depletion or there is an inability to reabsorb Cl$^-$ explaining why NaCl and KCl do not correct the metabolic alkalosis in these individuals. Edematous states, such as congestive heart failure and cirrhosis, are also generally unresponsive to volume (and Cl$^-$) replacement, despite the reduction in effective arterial blood volume.
Mineralocorticoid Excess. Mineralocorticoids, such as aldosterone, act in the cortical collecting tubule (see Chapter 72), where they enhance Na–K exchange as well as H⁺ secretion. As a result, overproduction of an endogenous mineralocorticoid (as occurs in primary aldosteronism) or with the ingestion of a substance that can increase the mineralocorticoid activity of cortisol (e.g., glycyrrhizic acid in licorice) leads to hypokalemia and metabolic alkalosis. Hypertension is characteristically present in these disorders. In contrast to patients with secondary increases in mineralocorticoid activity (e.g., as in congestive heart failure), edema does not occur. This phenomenon, called aldosterone escape, results at least in part from the high renal interstitial pressures generated by the hypertension that limits further NaCl reabsorption; it is also possible that atrial natriuretic peptide, released in response to volume expansion, contributes to this phenomenon.

In addition to the direct effect of aldosterone on H⁺ secretion, hypokalemia also appears to be necessary for the maintenance of a significant metabolic alkalosis in patients with primary mineralocorticoid excess. The mechanism of this effect involves the development of intracellular acidosis with increased H⁺ secretion and HCO₃⁻ reabsorption by the proximal tubule and enhanced distal nephron Na–H exchange.

Severe Hypokalemia. The effect of mild-to-moderate hypokalemia on the generation and maintenance of metabolic alkalosis has been discussed. Severe hypokalemia (plasma K⁺ < 2 mEq per L) can additionally impair distal Cl⁻ reabsorption by an unknown mechanism. In this setting, some of the Na⁺ that is normally reabsorbed with Cl⁻ must be reabsorbed in exchange for H⁺.

Bartter’s and Gitelman’s Syndromes. Bartter’s syndrome is a rare cause of metabolic alkalosis typically seen in children and young adults. The loop of Henle appears to be the site responsible for this disorder. Metabolic alkalosis is also present in patients with Gitelman’s syndrome, in which the defect occurs in the thiazide-sensitive site of the distal tubule. In contrast to patients with primary aldosteronism, patients with Bartter’s and Gitelman’s syndromes are normotensive or slightly hypotensive. The associated volume depletion causes chronic activation of the renin–angiotensin–aldosterone system, increasing distal nephron K⁺ and H⁺ secretion, as in patients receiving a loop or thiazide diuretic.
Clinical Manifestations

Most patients with metabolic alkalosis do not suffer clinically from the effects of alkalemia [12]. When symptoms are present, they are typically those associated with volume depletion (e.g., weakness, muscle cramps, postural dizziness) or hypokalemia (e.g., muscle weakness, polyuria, polydipsia). The usual symptoms of alkalemia are because of increased neuromuscular excitability and are exhibited as paresthesias, carpopedal spasm, or lightheadedness, although these findings are relatively more common in patients with acute respiratory alkalosis.

Diagnosis

The cause of metabolic alkalosis can usually be elicited from the history and physical examination. One of the most important aspects of the physical examination in identifying a cause is the determination of blood pressure. Except for the hypertensive individual taking a diuretic, hypokalemia in the presence of metabolic alkalosis and hypertension should suggest the presence of a primary mineralocorticoid-induced disease, such as hyperaldosteronism. Normotensive individuals with no obvious cause most often have surreptitious vomiting or diuretic ingestion (pseudo-Bartter’s syndrome) as the precipitating event; Bartter’s and Gitelman’s syndromes are much rarer.

The urinary Cl⁻ concentration is important because urinary Na⁺ wasting may occur in the presence of a high plasma HCO₃⁻ concentration even if volume depletion is present. NaHCO₃⁻ losses develop when the plasma HCO₃⁻ level exceeds the renal reabsorptive threshold, a condition that obligates the excretion of HCO₃⁻ with a cation to maintain electroneutrality. The most abundant cation in the filtrate is Na⁺, even in low perfusion states. As a result, the urine Na⁺ concentration should not be used to infer the volume status of an individual with an increased plasma HCO₃⁻ concentration, unless it is less than 20 mEq per L. By comparison, the urinary Cl⁻ concentration characteristically is low in hypoperfusion states because Cl⁻ is not affected by bicarbonaturia.

Measurement of the urinary Cl⁻ concentration is useful in differentiating these disorders (Table 198.5). The urinary Cl⁻ concentration is typically less than 15 mEq per L, with hypovolemia caused by vomiting or diuretic therapy (if the effect of the diuretic has worn off). Higher values are found if the diuretic is still in effect, if Bartter’s or Gitelman’s syndromes or severe hypokalemia are present, or
if there is primary mineralocorticoid excess (e.g., primary aldosteronism). Diuretic abuse may be distinguished from Bartter’s or Gitelman’s syndromes in some cases by screening the urine for diuretics.

³Because the maintenance of metabolic alkalosis requires impairment of renal bicarbonate excretion, the pathophysiology of the renal limitation determines the urinary chloride concentration. If, for example, there is underlying hypovolemia, the urinary chloride concentration is low (<15 mEq/L); in comparison, the urinary chloride concentration is >20 mEq/L when the cause of renal bicarbonate retention is a reduction in glomerular filtration rate, as in the milk-alkali syndrome, or in patients with acute tubular necrosis who received large alkali loads.

Mixed Acid–Base Disturbances with Metabolic Alkalosis

**Respiratory Compensation.** The increased arterial pH in metabolic alkalosis leads to a compensatory rise in the PCO₂. This decrease in respiration is owing to direct suppression of the medullary respiratory center by alkalemia. In general, the PCO₂ rises approximately 0.7 mm Hg for every 1 mEq per L elevation in the plasma HCO₃⁻ concentration [14], a relationship that pertains until PCO₂ rises to approximately 60 mm Hg (corresponding to a plasma HCO₃⁻ concentration = 53 mEq per L); values above this level are unusual because further hypoventilation is limited by the development of hypoxemia. The identification of a PCO₂ greater or less than predicted suggests the presence of a second primary acid–base disturbance, respiratory acidosis or respiratory alkalosis, respectively.

**Metabolic Alkalosis with Metabolic Acidosis.** As previously
discussed, the ratio of the increment in AG to decrement in the plasma HCO$_3^-$ concentration ($\Delta$AG/$\Delta$HCO$_3^-$) can be used to identify the presence of a metabolic alkalosis in a patient with metabolic acidosis. In such cases, the increment in the serum AG is more than twofold greater in magnitude than the apparent fall in the bicarbonate level.

**Treatment of Metabolic Alkalosis**

Rapid correction of metabolic alkalosis is usually not necessary because of the general rarity of adverse effects directly related to the rise in pH. As a result, there is ordinarily time to identify the cause of the disorder and to institute specific therapy. Any exogenous sources of alkali (e.g., preparations containing HCO$_3^-$, acetate, lactate, or citrate) should be discontinued.

Because hypomagnesemia may be present in some patients with metabolic alkalosis, a serum magnesium level should be checked, particularly in patients with refractory hypokalemia, because hypomagnesemia predisposes to renal potassium wasting.

**Chloride-Responsive Metabolic Alkalosis**

Chloride replacement (as NaCl or KCl or both) is appropriate for management of most individuals with a low urinary Cl$^-$ concentration. Administration of Cl$^-$-containing fluid with K$^+$ ameliorates the alkalosis by permitting renal excretion of the excess HCO$_3^-$.$^1$ It allows more Na$^+$ to be reabsorbed with Cl$^-$, rather than in exchange for H$^+$; it reduces the volume stimulus for Na$^+$ retention, permitting HCO$_3^-$ excretion in the urine; and it increases the plasma K$^+$ concentration, which raises the tubular cell pH and reduces renal H$^+$ secretion. Replacement of the volume deficit with non–Cl$^-$-containing solutions of Na$^+$ or K$^+$ does not correct the alkalosis or hypokalemia because non-Cl$^-$ anions obligate further K$^+$ and H$^+$ excretion. Patients with vomiting or nasogastric suction may also benefit from H$_2$-blockers or other medications that reduce gastric acid secretion. They are not, however, substitutes for Cl$^-$ replacement, which is still necessary to correct the already present chloride deficit.
The therapy of metabolic alkalosis in edematous patients (e.g., those with congestive heart failure and advanced liver disease) is more difficult. Although renal perfusion is characteristically reduced, leading to a low urinary Cl\(^-\) concentration, Cl\(^-\) administration (e.g., as 0.9% saline) does not enhance HCO\(_3\)^- excretion because the reduced effective arterial blood volume is not corrected by this therapy. In this setting, the carbonic anhydrase inhibitor acetazolamide (at a dose of 250 to 500 mg once- or twice-daily orally or intravenously) may be useful because it permits fluid mobilization while decreasing HCO\(_3\)^- reabsorption in the proximal tubule. An adverse consequence of acetazolamide administration is the tendency for more K\(^+\) wasting. Careful monitoring of the plasma K\(^+\) concentration is necessary. When the plasma K\(^+\) level is low, the use of a distally acting K\(^+\)-sparing diuretic (e.g., amiloride or spironolactone) can be considered.

In extremely rare instances, these maneuvers may be insufficient, or the metabolic alkalosis may be so severe that adverse neurologic symptoms of alkalemia are present. In such instances, HCl can be given intravenously to lower the plasma HCO\(_3\)^- concentration. HCl is usually given as a solution isotonic to plasma (150 mEq H\(^+\) and 150 mEq Cl\(^-\) in each liter of distilled H\(_2\)O). The volume needed to reduce the plasma HCO\(_3\)^- concentration can be estimated from calculation of the HCO\(_3\)^- excess. Because the volume of distribution of HCO\(_3\)^- is approximately 50% of the lean body weight, the amount of HCl needed to lower the plasma HCO\(_3\)^- concentration from 45 to 35 mEq per L in a 70-kg man can be calculated as follows (assuming there are no ongoing HCO\(_3\)^- losses):

\[
\text{HCO}_3^- \text{ excess} = 0.5 \times 70 \, \text{L} \times (45 - 35 \, \text{mEq/L}) = 350 \, \text{mEq}
\]

This would require administration of slightly more than 2 L of an isotonic HCl solution. Because the very low pH of this solution can injure small veins and tissues, particularly if extravasation occurs, administration should generally occur over at least 24 hours using a large (central) vein. As a result, the administration of HCl may outweigh the potential benefits.

Dialytic therapy may be helpful in the unusual patient presenting with metabolic alkalosis, volume overload, and renal failure. Peritoneal dialysis typically contains lactate as the HCO\(_3\)^- precursor at a concentration of approximately 40 mEq per L, an amount that may worsen the alkalosis. By comparison, the alkali level can be adjusted with
most current hemodialysis machines. It is important to note that citrate used for anticoagulation in some continuous dialytic therapies can lead to metabolic alkalosis as well [13].

**Chloride-Resistant Metabolic Alkalosis**

Individuals with a urinary chloride concentration greater than 15 mEq per L are unlikely to respond to Cl\(^{-}\)-containing solutions such as physiologic saline, with correction of the metabolic alkalosis. Because the effective renal blood flow is already normal or Cl\(^{-}\) reabsorption must be impaired, the administered Cl\(^{-}\) is rapidly excreted in the urine. Moreover, enhanced distal Na\(^{+}\) presentation increases Na–K exchange, leading to a rise in urinary K\(^{+}\) excretion with more severe hypokalemia in states of primary mineralocorticoid excess.

In a hypertensive patient, primary aldosteronism should be considered. Removing the source of aldosterone (by adrenalectomy when an aldosterone-secreting adenoma is present) or blocking its action (with a K\(^{+}\)-sparing diuretic, such as spironolactone) is usually sufficient to correct the hypokalemia and metabolic alkalosis and to control hypertension in this disorder.

The abnormality in Bartter’s and Gitelman’s syndromes, impaired Cl\(^{-}\) reabsorption, cannot be corrected with treatment. Therapy is, therefore, directed at improving the laboratory abnormalities, particularly hypokalemia and metabolic alkalosis. Nonsteroidal anti-inflammatory drugs (including cyclooxygenase-2 inhibitors) reduce renin secretion (a prostaglandin-dependent process) and may be effective in correcting the plasma HCO\(_3\)\(^{-}\) and K\(^{+}\) levels to or near normal, although K\(^{+}\) supplementation may also be required. Angiotensin-converting enzyme inhibitors or K\(^{+}\)-sparing diuretics may be useful alone or in combination, but they have the potential risk of causing the already slightly low blood pressure to fall. It is important to exclude surreptitious diuretic use or forced vomiting in these individuals before assigning a diagnostic or therapeutic regimen used for Bartter’s syndrome or Gitelman’s syndrome because the former are far more common disorders.
REFERENCES

Hyponatremia and hypernatremia are conditions commonly observed in the intensive care unit. They are defined as plasma Na$^+$ concentration below 135 mEq per L and above 145 mEq per L, respectively. The correct management of patients with these disorders depends on an understanding of normal salt (NaCl) and water (H$_2$O) physiology.

It is important to appreciate that hyponatremia represents a disorder of water balance; the plasma sodium concentration reflects the ratio of water to sodium in the body. However, the presence of hyponatremia or hypernatremia cannot be used to assess the volume status of a patient. Furthermore, the plasma sodium concentration has little relationship to the urinary sodium concentration.

Hypothalamic osmoreceptors influence thirst and the release of antidiuretic hormone (ADH). The latter increases $U_{\text{Osm}}$, causing water retention by enhancing the permeability of the collecting tubules to water. ADH is also released in response to effective volume depletion (hypovolemia). Although water retention causes extracellular volume expansion, this is slight, as approximately two-thirds of the water enters the cells. As a result, volume-mediated ADH release can occur even in states of hyponatremia.

**Relationship Between Plasma Na$^+$ and Plasma Osmolality**

The osmolality of plasma ($P_{\text{Osm}}$) is determined by the sum of the osmolar contributions of the individual osmotically active substances. In plasma,
Na\(^+\) salts, glucose, and urea (blood urea nitrogen [BUN]) are the major determinants of osmolality. Therefore, the \(P_{\text{Osm}}\) can be estimated by the following formula:

\[
P_{\text{Osm}} \approx 2 \times \text{plasma Na}^+ + \frac{\text{glucose}}{18.0} + \frac{\text{BUN}}{2.8}
\]

Using this equation,\(^1\) it is evident that the major determinant of the \(P_{\text{Osm}}\) in healthy individuals is the plasma Na\(^+\) concentration.

The ability of a solute (such as sodium) to promote shifts of water between the intracellular and the extracellular compartments depends not only on its capacity to increase the \(P_{\text{Osm}}\) but also on its exclusion from one of these compartments. Because urea can cross almost all cell membranes readily, it cannot promote the movement of water between the intracellular and extracellular spaces. As such, urea is referred to as an ineffective osmole. A rise in the BUN is detected as an increase in the measured (by the laboratory) and calculated \(P_{\text{Osm}}\), but there is no change in the plasma Na\(^+\) concentration because urea does not obligate water movement from the intracellular to the extracellular space. Because urea is an ineffective osmole and because glucose normally contributes less than 8 mOsm per kg, the effective \(P_{\text{Osm}}\) correlates best with the plasma Na\(^+\). Thus, effective \(P_{\text{Osm}}\) can be described as follows:

\[
P_{\text{Osm}} \text{ (effective)} \approx 2 \times \text{plasma Na}^+ \text{ concentration}
\]

Sodium is confined primarily to the extracellular fluid by the Na-K antiporter present in most cells. This pump also maintains a high (approximately 130 mEq per L) intracellular K\(^+\) concentration; thus, potassium is the principal effective osmole inside cells. The ability of water to cross almost all cell membranes indicates that the \(P_{\text{Osm}}\) must be in equilibrium with the intracellular osmolality. In fact, osmolality is equal throughout all body compartments, explaining the need for only one osmoreceptor.

Because osmotic equilibrium exists throughout body water, calculation of water deficits or excesses, when dealing with a hyponatremic or hypernatremic individual, respectively, must be based on total body water (TBW) and not merely on the extracellular fluid volume. Moreover, loss of potassium from the body, as might occur with diuretic administration, affects the plasma Na\(^+\) concentration.

Two processes participate in the reduction in plasma Na\(^+\) concentration induced by potassium losses. Sodium movement into cells to maintain electroneutrality lowers the plasma Na\(^+\), and loss of
potassium from the gastrointestinal tract or kidneys causes a fall in the plasma potassium with a larger fall in the intracellular potassium. The result is a reduction in the intracellular osmolality that leads to water movement from cells to the extracellular compartment.

Finally, although plasma hypoosmolality is always associated with hyponatremia, a high P_{Osm} can occur in the absence of hypernatremia. Other ineffective osmoles (in addition to urea) have the ability to raise the measured P_{Osm} without affecting water shifts. The most important of these are the alcohols: ethanol, ethylene glycol, and methanol. By contrast, severe hyperglycemia can induce hyponatremia by pulling water out of cells, but the P_{Osm} will be elevated. This phenomenon, seen most often in diabetics, is referred to as hyperosmolar hyponatremia.

Regulation of Plasma Osmolality

Maintenance of the plasma Na^+ concentration within narrow limits (285 to 292 mOsm per kg) depends on the ability of the kidneys to excrete water and on a normal thirst mechanism with access to water. Under normal conditions, the quantity of water that can be excreted in the urine far exceeds the amount ingested. Renal water excretion is determined by two factors: urinary solute excretion and the ability to generate maximally dilute urine (U_{Osm} <100 mOsm per kg). The typical American diet affords a solute intake between 600 and 1,200 mOsm—average 900 mOsm—per day. Assuming an output that approximates intake, the daily urinary solute excretion of a typical adult would also average 900 mOsm. Dietary NaCl, KCl, and protein, which is broken down to urea, make up most of this solute load. The individual who excretes 900 mOsm of solute per day and who can dilute urine maximally (down to 50 mOsm per kg) has the capacity to excrete up to 18 L of water in a 24-hour period:

\[
900 \text{ mOsm/50 mOsm/kg} = 18 \text{ L}
\]

The capacity to dilute urine begins in the loop of Henle and continues to the collecting tubule. This portion of the nephron, which is impermeable to water, is often referred to as the **diluting segment** (Fig. 199.1). As filtrate passes through the loop of Henle, solute is removed by the Na/K/2Cl transporter located in the cells of thick ascending limb and by the NaCl carrier in the distal tubule. Filtrate leaving the diluting segment and entering the early collecting tubule characteristically is very
dilute, with a urinary osmolality ($U_{Osm}$) of less than 100 mOsm per kg.

![Diagram](image)

**FIGURE 199.1** Excretion of a dilute urine. Solute entering the early proximal tubule has an osmolality identical to that of plasma; fluid is isotonically reabsorbed in this nephron segment. Separation of solute from water ($H_2O$) within the tubule begins in the thick ascending limb of Henle, which is impermeable to $H_2O$. Excretion of urine with a minimum osmolality of 50 to 100 mOsm per L requires intact function of this nephron segment as well as suppression of antidiuretic hormone (ADH) release. (Adapted from Iwasaki Y, Oiso Y, Yamauchi K, et al: Osmoregulation of plasma vasopressin in myxedema. J Clin Endocrinol Metab 70:534, 1990.)

A maximally dilute urine cannot be excreted if the removal of salt by the pumps and carriers in the diluting segment is impaired or if the collecting tubule is rendered permeable to water by the presence of ADH. Inability to dilute the urine may have serious consequences. For example, for a patient unable to achieve urinary dilution below an osmolality of 300 mOsm per kg, the amount of water that can be excreted on a normal diet is reduced to 3 L:

$$900 \text{ mOsm} / 300 \text{ mOsm/kg} = 3 \text{ L}$$

As discussed earlier, solute excretion is normally determined by dietary intake. A reduction in dietary sodium and protein intake, as is seen in the patient on a “tea-and-toast” diet, limits the capacity to excrete water. If solute intake falls to 150 mOsm per day, for instance, water excretion is
limited to approximately 3 L even when urinary dilution is normal:

\[ 150 \text{ mOsm/50 mOsm/kg} = 3 \text{ L} \]

It is easy to see that the combination of impaired diluting ability with a concomitant reduction in solute intake is more likely to impair water excretion and result in hyponatremia than either disturbance alone.

**Regulation of Antidiuretic Hormone**

Healthy adults are able to excrete very large or very small volumes of urine, the concentration of which varies according to the \( P_{Osm} \). The primary hormone regulating water excretion in health is ADH. ADH (called arginine vasopressin in humans) is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. Hypothalamic osmoreceptors for ADH release are stimulated by hyperosmolality and inhibited by hypoosmolality. A change in osmoreceptor cell volume is probably the factor that modifies ADH secretion in response to changes in the \( P_{Osm} \). The concentration of urea, an ineffective osmole incapable of altering cell volume, does not affect ADH release.

A 1% to 2% reduction in \( P_{Osm} \) (\( P_{Osm} < 280 \text{ mOsm per kg} \)) maximally inhibits ADH release, leading to a \( U_{Osm} \) that is less than 100 mOsm per kg \[^1\]. By contrast, a 1% to 2% increase in \( P_{Osm} \) above normal, or a 7% to 10% decrease in blood pressure or volume (even in the presence of plasma hypoosmolality), stimulates ADH release. In the presence of ADH, the luminal membranes of the cortical and medullary collecting tubules become permeable because water channels (aquaporins) are inserted into the luminal membrane. Water can then pass into the surrounding medullary interstitium because of the osmotic gradient.

**Hyponatremia**

In most settings, the development of hyponatremia with hypoosmolality represents the retention of ingested or administered water. Thus, the causes of hyponatremia can be divided into those in which water excretion is abnormal and those in which water excretion is normal, but water ingestion is considerably increased.

**Hypoosmolar Disorders with Impaired Water Excretion**

The \( U_{Osm} \) is typically greater than 100 mOsm per kg in patients with reduced water excretion (Table 199.1). An exception to this rule occurs when solute intake is markedly reduced, as in the patient subsisting on a solute-poor diet.
TABLE 199.1 Causes of Hyponatremia

Impaired water excretion ($\text{U}_{\text{Osm}} >100 \text{ mOsm/kg}$ and usually $>300 \text{ mOsm/kg}$)

Hypovolemic states
- True volume depletion (by gastrointestinal, skin, or renal losses)
- Edematous states with reduced effective arterial blood volume (advanced liver and heart disease)

Diuretics (particularly thiazides)

Advanced chronic kidney disease

Endocrine deficiencies (hypothyroidism and hypoadrenalism)

Syndrome of inappropriate antidiuretic hormone secretion

Cerebral salt wasting

Reduced solute intake (tea-and-toast diet, beer drinkers’ hyponatremia)\textsuperscript{a}

Normal water excretion ($\text{U}_{\text{Osm}} <100 \text{ mOsm/kg}$)

Primary polydipsia
- Psychiatric disorders (particularly with phenothiazines)
- Hypothalamic disorders

Hyponatremia without hypoosmolality

Normal $\text{P}_{\text{Osm}}$

Pseudohyponatremia (hypertriglyceridemia, hyperproteinemia, genitourinary tract irrigation)

Increased $\text{P}_{\text{Osm}}$

Hyperosmolar hyponatremia (hyperglycemia, mannitol infusion in renal failure)

Azotemia (effective osmolality is reduced)

\textsuperscript{a}$\text{U}_{\text{Osm}} <100 \text{ mOsm/kg}$, but normal water excretion is impaired by the reduced solute load (see text for details).

$\text{P}_{\text{Osm}}$, osmolality of plasma; $\text{U}_{\text{Osm}}$, osmolality of urine.

Renal Hypoperfusion-Induced Hyponatremia. A fall in effective perfusion pressure stimulates release of ADH [2]. Hypovolemic hyponatremia can occur in states of volume depletion or in edematous individuals with congestive heart failure (CHF) or advanced liver disease because each of these conditions is associated with a reduced effective arterial blood volume. As discussed previously, the resulting increase in the \( \text{U}_{\text{Osm}} \) (e.g., to 600 mOsm per kg) would limit renal water excretion on a 900 mOsm per day diet to 1.5 L, assuming all of the ingested solute were excreted (900/600 mOsm per kg). Solute excretion tends to be reduced in these settings, which are characterized by enhanced tubular salt reabsorption. In addition, most stimuli that activate angiotensin II release stimulate thirst and lead to increased water ingestion, despite concurrent hypoosmolality.

Diuretic-Induced Hyponatremia. The ability to excrete dilute urine is impaired by diuretics, whether they act in the thick ascending limb of Henle (loop diuretics) or in the distal tubule (thiazide diuretics) (Fig. 199.2). Each class reduces salt transport out of the diluting segment, thus raising the minimum achievable \( \text{U}_{\text{Osm}} \). Raising the minimum \( \text{U}_{\text{Osm}} \) however, does not usually lead to hyponatremia because a large volume of urine can still be excreted by most patients.

**FIGURE 199.2** Site of action of loop and thiazide diuretics. Loop diuretics inhibit the Na-K-2Cl.
cotransporter in the medullary portion of the thick ascending limb of Henle, whereas thiazides block a simple NaCl carrier in the cortical portion of the distal tubule. These differences explain, in part, the susceptibility of individuals treated with thiazide-type diuretics to the development of hyponatremia (see text for details).

Almost all cases of diuretic-induced hyponatremia in otherwise healthy individuals have been caused by thiazide, rather than loop, diuretics. This observation is attributable, in part, to different sites of the action within the renal tubule (Fig. 199.2). Loop diuretics, which act in the outer medulla, reduce the solute concentration in the renal medullary interstitium. Although ADH permits water reabsorption from the collecting tubule, medullary osmolality drives the process. A fall in the interstitial osmolality from 1,200 to 300 mOsm per kg, for instance, would limit the maximum U_{Osm} that can be generated from 1,200 to 300 mOsm per kg. By comparison, thiazide diuretics, which act in the cortex, impair diluting capacity but have a lesser effect on concentrating ability. Thus, the U_{Osm} may be 600 mOsm per kg in the thiazide-treated individual; if the urinary osmoles are primarily NaCl and KCl, urinary electrolyte losses can exceed those contained in an equal volume of plasma. In these patients, therefore, the plasma Na^+ may actually fall in the absence of ongoing water intake. For reasons that are not well understood, however, most individuals with thiazide-induced hyponatremia gain weight, indicating that the hyponatremia is at least in part a result of increased water intake. This disorder occurs more frequently in women, typically occurs early in therapy (within 1 to 4 weeks), and is more likely to be observed in elderly individuals [3]. As discussed previously, accompanying hypokalemia may also contribute to the fall in P_{Osm}.

**Advanced Chronic Kidney Disease.** The normal glomerular filtration rate (GFR) is approximately 180 L per day. As renal function decreases, the ability to excrete water also decreases. The limitation in water excretion occurs for two reasons: tubular dysfunction leads to an inability to dilute the urine maximally, even in the absence of ADH, and the drop in GFR, particularly when severe, reduces daily solute excretion.

**Endocrine Deficiency.** Hypothyroidism and hypocortisolism can impair water excretion. Both may reduce cardiac output or stroke volume, leading to increased ADH release. The resulting fall in GFR
adversely affects free water excretion by diminishing delivery of filtrate to the diluting segments. Decreased delivery may be particularly important in patients with myxedema in whom hyponatremia may develop despite appropriate suppression of ADH release [4].

Another factor contributing to the hyponatremia of hypocortisolism is that corticotropin-releasing factor promotes the co-release of adrenocorticotropic hormone (ACTH) and ADH [5]. It is important to note that adrenocortical dysfunction (as in Addison’s disease) leads to reduced cortisol and aldosterone levels, the latter predisposing to hyperkalemia. The presence of a low cortisol level alone, because of either pituitary or hypothalamic disease, or the abrupt withdrawal from prolonged exogenous corticosteroid administration may cause hyponatremia but should not alter potassium homeostasis, because aldosterone release is normal.

Syndrome of Inappropriate Antidiuretic Hormone Secretion. The syndrome of inappropriate ADH secretion (SIADH) is characterized by the following: plasma hypoosmolality, $U_{\text{Osm}}$ more than 100 to 150 mOsm per kg (because ADH should be absent in the hypoosmolar state), urinary $\text{Na}^+$ concentration of more than 20 mEq per L (reflecting normal renal perfusion); normal adrenal, renal, and thyroid function; and normal potassium and acid–base balance. The $U_{\text{Osm}}$ does not need to exceed the $P_{\text{Osm}}$ to make this diagnosis. SIADH may be caused by enhanced hypothalamic ADH secretion, ectopic hormone production (usually by cancer), or administration of medications with ADH activity (Table 199.2).

<sup>a</sup>Hyponatremia induced by cisplatin may be because of renal salt wasting.

ADH, antidiuretic hormone; SSRIs, selective serotonin reuptake inhibitors.

In approximately one-third of patients, SIADH is associated with resetting of the hypothalamic osmostat. This disorder has been described in patients with hypovolemia, psychosis, and chronic malnutrition, as well as in normal pregnancy (in which the plasma Na<sup>+</sup> concentration decreases by the second trimester from 140 to 135 mEq per L). ADH release is not suppressed until the P<sub>Osm</sub> falls well below normal in this disorder. As a result, the P<sub>Osm</sub> may vary between 240 and 250 mOsm per kg (plasma Na<sup>+</sup> approximately 120 to 125 mEq per L), compared with the normal value of approximately 285 to 292 mOsm per kg. In contrast to the classic form of the SIADH, in which nonsuppressible ADH release is seen, ADH secretion ceases when the P<sub>Osm</sub> falls below this new, reset level. Because suppression of ADH prevents a further fall in the plasma Na<sup>+</sup> concentration, the severity of hyponatremia is limited in this condition.

The presence of a reset osmostat should be suspected in any patient with apparent SIADH who has mild hyponatremia (usually between 125 and 135 mEq per L) that is stable over many days despite variations in
sodium and water intake. The diagnosis can be confirmed clinically by observing the response to a water load (10 to 15 mL per kg given orally or intravenously during 30 minutes). Healthy subjects and those with a reset osmostat should excrete more than 80% within 4 hours, whereas excretion is impaired in classic SIADH.

Elevated ADH levels have been reported with the use of medications and various recreational drugs. Hyponatremia associated with ingestion of 3,4-methylenedioxy-methamphetamine (Ecstasy) is reportedly caused by increased water drinking and inappropriate ADH and has led to fatalities [1]. Similar effects may be seen with the commonly prescribed selective serotonin reuptake inhibitors (SSRIs) used for the treatment of depression [6].

Cerebral Salt Wasting. Cerebral salt wasting is a rare disorder characterized by a low $P_{\text{Osm}}$, a $U_{\text{Osm}}$ above 100 to 150 mOsm per kg, and a urine Na$^+$ concentration greater than 20 mEq per L. Unlike SIADH, however, evidence of volume depletion (including low central filling pressures) is present. In affected individuals, therefore, the high urinary Na$^+$ represents inappropriate salt wasting rather than a response to normal tissue perfusion (as in SIADH patients). The cause of this putative syndrome is unclear. Mineralocorticoid replacement therapy with fludrocortisone acetate has been effective in some patients.

Reduced Solute Intake. As discussed previously, a reduction in salt and protein intake can lead to hypoosmolality if water intake exceeds output. Severely reduced solute intake, as occurs with a “tea-and-toast diet,” can cause hyponatremia even with normal degrees of water intake. “Beer drinkers’ hyponatremia” occurs for a similar reason; the limited amount of solute in beer relative to its water content may be inadequate to permit excretion of the ingested water. In both conditions, the $U_{\text{Osm}}$ should be maximally dilute ($U_{\text{Osm}}$ <100 mOsm per kg). The absence of polyuria and the development of hyponatremia with normal or slightly above normal fluid intake distinguish these individuals from those with primary polydipsia.

Hypoosmolar Disorders with Normal Water Excretion. Psychiatric patients, particularly those with schizophrenia, often have abnormalities in water balance. Evaluation of psychotic patients has revealed that a variety of defects in water handling can occur that affect thirst, the release of ADH, and the renal response to ADH. Depending on the abnormality that is present, the patient may present with polydipsia and polyuria or hyponatremia.
Hyponatremia has been reported in as many as 13% of marathon runners and may occasionally be fatal. Although the exact mechanism has not been elucidated, risk factors for developing low serum sodium levels include weight gain during the race, female sex, racing time, and lower body mass index [7]. Exercise-induced hyponatremia has been described after intense physical activity during marathons, triathlons, and high-intensity competitions. Again, the pathophysiology involves a combination of excessive fluid intake as well as a defect in renal water excretion. Athletes have been encouraged to drink more fluids c/w recommendations 30 years ago [8]. There may be a variety of pathways that stimulate ADH secretion, including muscle injury and release of cytokines with vigorous activity.

**Primary Polydipsia.** This disorder is most often seen in anxious, middle-aged women and in patients with psychiatric illnesses, including those taking medications that can lead to the sensation of dry mouth. These individuals drink large volumes of water for social, dietary, or health reasons. This may be manifested clinically by exaggerated weight gain during the day associated with a transient reduction in the plasma sodium concentration. Primary polydipsia can also be induced by hypothalamic lesions that directly affect the thirst center, as may occur with an infiltrative disease such as sarcoidosis. For example, the osmotic threshold for thirst may be reduced below the threshold for the release of ADH. These patients continue to drink until the $P_{\text{Osm}}$ is less than the threshold level. This implies truly prodigious water intake, because ADH secretion is suppressed by the fall in $P_{\text{Osm}}$, resulting in rapid excretion of the excess water. The mechanism responsible for abnormal thirst regulation in this setting is unclear. Drug therapy may contribute to the increase in water intake if the medication induces the sensation of a dry mouth.

Because people with normally functioning kidneys and regulation of ADH secretion are capable of excreting more than 10 to 15 L of urine per day, hyponatremia as a result of polydipsia is unusual. Despite this, there are rare patients in whom severe, and potentially fatal, hyponatremia has developed even though the $U_{\text{Osm}}$ was appropriately dilute. More commonly, however, polydipsic patients manifesting hyponatremia have a concurrent abnormality in ADH release or response. Concurrent thiazide diuretic therapy for systemic hypertension can lead to a marked and symptomatic reduction in the plasma sodium concentration in these patients.
Hyponatremia Without Hypoosmolality

Hyponatremia may occur without plasma hypoosmolality. An increase in the plasma concentration of proteins (as immunoglobulins in multiple myeloma) or lipids (primarily triglycerides in lipemic plasma) can reduce the plasma Na\(^+\) concentration. Lipids and proteins displace water from a given volume of plasma but do not affect the Na\(^+\) concentration in the water phase of plasma. As a result, the measured P\(_{Osm}\) is normal in this condition, which is called *pseudohyponatremia*. Because the sodium concentration in the aqueous component of plasma is normal, this form of hyponatremia is not of pathophysiologic consequence. The methods of electrolyte determination currently used in many laboratories (ion-selective electrodes) are not affected by plasma lipids or proteins.

An unusual form of hyponatremia, sometimes associated with a normal P\(_{Osm}\) but occasionally with hypoosmolality, can occur after transurethral prostatectomy, uterine irrigation after endometrial ablation, or with lithotripsy [9–11], which often requires the use of as much as 20 to 30 L of nonconductive flushing solutions containing glycine, sorbitol, or mannitol. Some patients absorb 3 L or more of fluid through the exposed mucosal vascular plexus, leading to a dilutional reduction in the plasma sodium concentration that may fall below 100 mEq per L. Even when P\(_{Osm}\) is not notably reduced, confusion, disorientation, twitching, seizures, and hypotension may occur. Several methods have been devised to attempt to monitor the amount of fluid absorbed so that patients at risk for severe hyponatremia can be detected. Frequent determinations of the plasma sodium concentration are important.

There are instances in which patients with plasma hyperosmolality may develop hyponatremia (*hyperosmolar hyponatremia*). This most commonly occurs with severe hyperglycemia or when mannitol is given to patients with renal failure, resulting in an osmotic shift of water from cells into the extracellular fluid, diluting the plasma Na\(^+\) concentration. In contrast to hypoosmolar hyponatremia, treatment is directed at correcting the high glucose concentration with insulin and free water repletion because cellular dehydration is present. For every 100 mg per dL rise in the blood sugar, the plasma Na\(^+\) concentration falls by approximately 1.6 mEq per L, although this estimate varies with body size, falling more in a smaller individual.

**Symptoms of Hypoosmolality**

The neurologic manifestations of hyponatremia appear to be entirely because of the consequences of plasma hypoosmolality. A fall in P\(_{Osm}\)
causes water movement from the extracellular space into cells. The resulting increase in cell water, which is of particular importance in the central nervous system, can lead to brain swelling. A variety of symptoms may be found, including lethargy, confusion, nausea, vomiting, and, in severe cases, seizures and coma. Focal neurologic symptoms are uncommon. Hyponatremic encephalopathy is generally reversible, although permanent neurologic damage or death has been reported, chiefly in premenopausal women [12]. Hyponatremic women may progress rapidly from minimal symptoms (such as headache and nausea) to respiratory arrest. Cerebral edema and herniation have been found in those women who died, suggesting a possible hormonally mediated decrease in the efficiency of the osmotic adaptation. The reason for the higher morbidity in this patient population is not well understood.

The likelihood that symptoms will develop is related to the level of hyponatremia and the rapidity with which it develops. For example, a rapid decline in the plasma Na\(^+\) concentration during several hours or days (e.g., from 140 to 115 mEq per L) may be associated with severe neurologic findings. In comparison, a similar fall in plasma sodium occurring during 1 week or more may not cause any symptoms. In the latter circumstance, the degree of cerebral edema is much less. This protective response, which begins on the first day and is complete within several days, occurs in two major steps:

1. The initial cerebral edema elevates the interstitial hydraulic pressure, creating a gradient for extracellular fluid movement out of the brain into the cerebrospinal fluid.

2. The brain cells lose solutes, leading to the osmotic movement of water out of the cells and less brain swelling [13]. The volume regulatory response begins with the movement of potassium and sodium salts out of the cells, followed by organic solutes, particularly the amino acids glutamine, glutamate, and taurine, and, to a lesser degree, the carbohydrate inositol. Electrolyte movement occurs quickly because it is mediated by the activation of quiescent cation channels in the cell membrane; organic solute loss occurs later because it requires synthesis of new transporters.

The organic solutes (called osmolytes) account for approximately one-third of the cellular solute loss in chronic hyponatremia. Changes in the concentration of these solutes offer the advantage of restoring cell volume without interfering with protein function; in comparison, a potentially deleterious effect on protein function would occur if the volume adaptation was mediated entirely by changes in the cell cation (potassium plus sodium) concentration.
This adaptation is so efficient that it is not uncommon to see patients with heart failure or SIADH who are asymptomatic despite a plasma sodium concentration of 115 to 120 mEq per L. The occurrence of symptoms in patients with chronic hyponatremia usually signifies a profoundly low serum sodium concentration of less than 110 to 115 mEq per L.

**Diagnosis of Hyponatremia**

Three laboratory findings provide important information in the differential diagnosis of hyponatremia: $P_{Osm}$, $U_{Osm}$, and urinary sodium concentration.

**Plasma Osmolality**

Because $P_{Osm}$ is mainly determined by the plasma sodium concentration, it is reduced in most hyponatremic patients. In some cases, however, the $P_{Osm}$ is either normal (as in pseudohyponatremia) or elevated (as in hyperosmolar hyponatremia).

**Urine Osmolality**

In patients with hypoosmolar hyponatremia, the $U_{Osm}$ can be used to distinguish between patients with impaired water excretion, accounting for most cases, and primary polydipsia, in which water excretion is normal but intake is so high that it exceeds excretory capacity. Hyponatremia caused by primary polydipsia should completely suppress ADH secretion, resulting in the excretion of maximally dilute urine with an osmolality less than 100 mOsm per kg and a specific gravity less than 1.003. A higher $U_{Osm}$ indicates an inability to excrete free water normally, which suggests continued secretion of ADH.

**Urinary Sodium Concentration**

The two major causes of hyponatremia are hypovolemia and SIADH. These disorders can usually be distinguished by measuring the urinary sodium concentration. The urinary sodium concentration of patients with hypovolemia is typically less than 20 mEq per L, assuming the patient is not receiving diuretics. Because patients with SIADH have normal renal
perfusion, unless they are on a very low sodium intake, the urinary sodium concentration is greater than 40 mEq per L. Patients with the SIADH can conserve urinary sodium normally and raise the urine osmolality further if intravascular volume depletion occurs.

The fractional excretion of sodium (FENa) is typically used as an assessment of volume status in acute kidney injury; in this setting, a level less than 1% suggests volume depletion. However, with normal kidney function, the expected value of FENa in euvolemia is less than 1%. As a result, random urinary sodium concentration is more accurate. FENa should not be used in the workup of hyponatremia.

Evaluation of acid–base and potassium balance may aid in the diagnosis in some hyponatremic patients. As examples, metabolic alkalosis and hypokalemia suggest diuretic use or vomiting; metabolic acidosis and hypokalemia suggest diarrhea or laxative abuse; and metabolic acidosis and hyperkalemia suggest adrenal insufficiency. On the contrary, plasma bicarbonate and potassium concentrations are typically normal in patients with SIADH. Although water retention tends to lower these values by dilution, as it does the plasma sodium and chloride concentrations, normal levels are restored by the factors that normally regulate acid–base and potassium balance.

The initial water retention and volume expansion in patients with SIADH are typically associated with hypouricemia (plasma uric acid concentration of ≤3 mg per dL) because of increased uric acid excretion in urine. In addition, urinary urea losses may cause a fall in the BUN to less than 5 mg per dL. These findings are the opposite of what is typically seen in volume depletion and thiazide-induced hyponatremia.

All of the findings seen in SIADH have also been described in the controversial syndrome of cerebral salt wasting, a disorder in which the high urinary sodium concentration occurs as a result of defective tubular reabsorption, and the elevation in ADH and subsequent development of hyponatremia are because of the associated volume depletion. Hypouricemia may also be present, which presumably is another manifestation of impaired renal tubular function.

Treatment of Hyponatremia

Saline or Water Restriction

In general, the plasma sodium concentration can be raised by giving patients salt (either as saline or salt tablets) or by restricting their water intake to below the level of excretion. The choice of therapy is primarily governed by the cause of the hyponatremia. The more recent additions of antagonists to the ADH receptor in the collecting tubule (vaptans) are also discussed.
Salt administration, usually as isotonic saline, is appropriate in those with true volume depletion or adrenal insufficiency, in which cortisol replacement is also indicated. Water restriction is used in patients without neurologic symptoms who have edematous states such as heart failure and hepatic cirrhosis and in those with SIADH, primary polydipsia, or advanced chronic kidney disease.

With volume depletion, isotonic saline corrects the hyponatremia by two mechanisms. Each liter of saline infused raises the plasma sodium by 1 to 2 mEq per L because saline has a higher sodium concentration (154 mEq per L) than plasma. In addition, volume repletion removes the stimulus to ADH release, thereby allowing the water surfeit to be excreted. At this time, the plasma sodium concentration will return rapidly toward normal.

In primary polydipsia, the initiation of water restriction may result in a dramatic rise in the plasma sodium concentration. These patients may be less predisposed to osmotic demyelination because their hyponatremia often is of rapid onset, with less brain cell adaptation apt to occur.

The optimal rate of correction of hyponatremia varies with the clinical state of the patient. In asymptomatic patients, who are more likely to have chronic hyponatremia, the plasma sodium concentration should be raised at a maximum rate of approximately 0.5 mEq/L/h and less than 8 mEq/L/d. A more rapid rise can increase the risk of osmotic demyelination.

More rapid initial correction is indicated for patients with symptomatic hyponatremia, particularly those presenting with seizures or other severe neurologic manifestations, which primarily result from cerebral edema induced by acute (developing during 2 to 3 days) hyponatremia. Here, the plasma sodium concentration can be raised at an initial rate of 1.5 to 2.0 mEq/L/h for the first 3 to 4 hours (or longer, if the patient remains symptomatic) because the risk of persistent severe hyponatremia outweighs that of overly rapid correction. This appears to be particularly important in premenopausal women, who may progress from minimal symptoms (headache and nausea) to coma and respiratory arrest; furthermore, irreversible neurologic damage or death is relatively common in younger women with symptomatic hyponatremia, even if the hyponatremia is corrected at an appropriate rate. In comparison, men are at much less risk of symptomatic hyponatremia and of permanent neurologic injury. After the initial 3 to 4 hours of rapid correction, the rate should be slowed down so that the total rise in plasma sodium does not exceed approximately 8 mEq during the initial 24 hours.

The quantity of sodium required to achieve the desired elevation in the plasma sodium concentration can be estimated from the product of the plasma sodium deficit per liter and the TBW, which represents the osmotic space of distribution of the
plasma sodium concentration. Normal values for the TBW are 0.5 and 0.6 times the lean body weight in women and men, respectively. If the initial aim in an asymptomatic hyponatremic 60-kg woman is to raise the plasma sodium concentration from 110 to 120 mEq per L, then

\[
\text{Sodium deficit for initial therapy} = 0.5 \times 60 \times (120 - 110) = 300 \text{ mEq}
\]

Thus, 600 mL of 3% hypertonic saline (which contains roughly 1 mEq of sodium per 2 mL, 500 mEq Na, and 500 mEq Cl per L) should be given during 20 hours at a rate of 30 mL per hour. This regimen should raise the plasma sodium concentration at the desired rate of 0.5 mEq/L/h, and serial monitoring of the plasma sodium concentration (beginning at 2 to 3 hours) is still required.

The preceding formula may be less accurate in patients with SIADH [3]. In this setting, the administered salt in the hypertonic 3% saline is excreted because plasma volume expansion is present. Therefore, the rise in plasma sodium is not because of sodium retention. Because there are approximately 1,000 mEq of solute (Na and Cl) in a liter of 3% saline, the fluid in the renal collecting tubule is relatively hyperosmotic. This causes water to be retained in the urine and excreted simultaneously with the salt load. If, for example, the \( U_{\text{Osm}} \) were 500 mOsm per kg, the 1,000 mEq of salt excreted would obligate the elimination of 2 L of urine (a net loss of 1 L of free water, because 1 L of water was administered with the hypertonic saline). The result would be no change in total body sodium and that the plasma sodium concentration would increase because of the loss of 1 L of water. Administration of the same hypertonic saline solution to an individual with SIADH and a \( U_{\text{Osm}} \) of 250 mOsm per kg would result in the loss of 4 L of urine (a net water loss of 3 L). The serum sodium would increase by a greater amount than it did in the person with the higher \( U_{\text{Osm}} \). As a consequence of the excretion of the salt load and varying levels of \( U_{\text{Osm}} \) in patients with SIADH, the sodium replacement formula is frequently misleading in this setting.

**Effects of Potassium**

Potassium is as osmotically active as sodium, and giving potassium can raise the plasma sodium concentration and osmolality in a hyponatremic subject. Because most of the excess potassium goes into the cells, electroneutrality is maintained in one of three ways, each of which raises the plasma sodium concentration: (a) intracellular sodium moves into the
extracellular fluid; (b) extracellular chloride moves into the cells with potassium; the increase in cell osmolality promotes free water entry into the cells; and (c) intracellular hydrogen moves into the extracellular fluid. These hydrogen ions are buffered by extracellular bicarbonate and, to a much lesser degree, by plasma proteins. This buffering renders the hydrogen ions osmotically inactive; the ensuing fall in extracellular osmolality leads to water movement into the cells.

Thus, any administration of potassium must be taken into account when calculating the sodium deficit. This relationship becomes clinically important in the patient with severe diuretic or vomiting-induced hyponatremia who is also hypokalemic.

Risk of Osmotic Demyelination

Severe hyponatremia, especially if acute in onset, can lead to cerebral edema, potentially irreversible neurologic damage, and death. This most often occurs when large volumes of hypotonic fluids are given to postoperative patients who have pain-induced ADH release that impairs the ability of the kidneys to excrete water or to patients with acute thiazide-induced hyponatremia. Within 24 hours, however, the brain begins to lose extracellular water into the cerebrospinal fluid and loses intracellular water by extruding sodium and potassium salts and osmolytes, thereby lowering the brain volume toward normal.

Hyponatremia that develops slowly (i.e., during >2 to 3 days) is associated with a lesser likelihood of neurologic symptoms. In this setting, in which brain volume has fallen toward normal, rapid correction of severe hyponatremia may lead within 1 to several days to the development of a neurologic disorder called osmotic demyelination or central pontine myelinolysis. These lesions are detectable by cerebral computed tomography or magnetic resonance imaging. Results of these diagnostic tests may not become positive for as long as 4 weeks, however [14].

The mechanisms responsible for osmotic demyelination are not completely understood. Rapid elevation in the plasma sodium concentration leads to water movement out of the brain, which can lower the brain volume below normal. Such osmotically induced shrinkage in axons could sever their connections with surrounding myelin sheaths. Alternatively, the initial brain cell response to brain shrinkage may be the uptake of potassium and sodium from the extracellular fluid; this elevation in cell cation concentration could be toxic to the cells.

The manifestations of osmotic demyelination, which may be irreversible, include mental status changes, dysarthria, dysphagia, paraparesis or quadriparenesis, and coma; seizures may occur but are less common. Patients in whom the plasma sodium concentration is raised to
more than 20 mEq per L in the first 24 hours or is overcorrected to greater than 140 mEq per L are at greatest risk. Other putative risk factors for osmotic demyelination include chronic alcoholism, malnutrition, prolonged diuretic use, liver failure and transplantation, and burns [15]. On the contrary, late neurologic deterioration is rare if the hyponatremia is corrected at an average rate equal to or less than 0.5 mEq/L/h [2].

Studies in experimental animals indicate that the total rate of correction during the first 24 hours is more important than the maximum rate in any given hour [16]. Demyelinating lesions are most common when the plasma sodium concentration in severe hyponatremia is raised by more than 20 mEq/L/d and are rare at a rate less than 10 to 12 mEq/L/d. This is similar to the safe average rate of correction of 0.5 mEq/L/h observed in humans.

Recommendations

The preferred rate at which the plasma sodium concentration should be increased varies with the clinical presentation. Owing to the cerebral adaptation previously described, patients with chronic asymptomatic hyponatremia are generally at little risk for neurologic symptoms. In this setting, rapid correction is not indicated and may be harmful. Although the optimal rate of correction is not clearly proven, the current recommendation in asymptomatic patients is that the plasma sodium concentration be raised at a maximum rate of 4 to 8 mEq/L/d (which represents an average correction of 0.5 mEq/L/h). Although it may be safe to increase the plasma sodium concentration at a rate of more than 8 mEq per day, there is no reason to correct it more rapidly in the absence of symptoms.

It is not known whether there is a potential benefit to administering water to previously hypoosmolar patients whose hyponatremia has been corrected much too rapidly. In rodents, a marked reduction in the incidence and severity of brain lesions was demonstrated if overly rapid correction (30 mEq per L or more during several hours) was partially reversed so that the net daily elevation in the plasma sodium concentration was less than 20 mEq per L [17]. This improvement was seen if therapy was begun before the onset of neurologic symptoms; benefit was much less likely in animals with symptomatic demyelination. The applicability of these findings to humans is uncertain.

More aggressive initial correction, at a rate of 1.5 to 2.0 mEq/L/h, is indicated for the first 3 to 4 hours (or until the symptoms resolve) in patients who present with seizures or other severe neurologic abnormalities as a result of untreated and usually acute hyponatremia. The primary problem in these patients is cerebral edema, and the risk of
delayed therapy is greater than the potential risk of too rapid correction. Even in this setting, however, the plasma sodium concentration should probably not be raised by more than 8 mEq per L in the first 24 hours because partial cerebral adaptation has already occurred. It is usually not necessary to continue hypertonic saline once the plasma sodium concentration is greater than 120 mEq per L.

**Treatment of Hyponatremia for the Syndrome of Inappropriate Antidiuretic Hormone Secretion.** Hyponatremia for the SIADH results primarily from ADH-induced retention of ingested water. Appropriate therapy for this disorder depends on the severity of the hyponatremia and, on the fact that, although water excretion is impaired, sodium handling is intact because there is no abnormality in volume-regulating mechanisms such as the renin–angiotensin–aldosterone system. Water restriction is the mainstay of therapy in asymptomatic hyponatremia of chronic SIADH. The associated negative water balance raises the plasma sodium concentration toward normal.

Severe, symptomatic, or resistant hyponatremia often requires the administration of salt. If the plasma sodium concentration is to be elevated, the osmolality of the fluid given must exceed that of the urine. This can be illustrated by a simple example (Table 199.3). Suppose a patient with SIADH and hyponatremia has a $U_{Osm}$ that cannot be reduced below 616 mOsm per kg. If 1,000 mL of isotonic saline is given (containing 154 mEq each of Na and Cl or 308 mOsm), all of the salt is excreted (because sodium handling is intact), but in only 500 mL of water (308 mOsm in 500 mL of water equals 616 mOsm per kg). The retention of half of the administered water leads to a further reduction in the plasma sodium concentration. As a result, correction of the hyponatremia for these cases requires the administration of hypertonic 3% saline intravenously or salt tablets orally, preferably in combination with a drug that lowers the $U_{Osm}$ and increases water excretion by impairing the renal responsiveness to ADH. A loop diuretic is most often used for this purpose.

This calculation assumes that the individual cannot dilute the urine below a urine osmolality of 616 mOsm/kg and that all the administered solute is excreted in the urine.

Demeclocycline and lithium act on the collecting tubule cell to diminish its responsiveness to ADH, thereby increasing water excretion. Demeclocycline may reduce aquaporin-2 expression in the renal inner medulla via cAMP generation [18]. These drugs tend to be too toxic (lithium) or ineffective (demeclocycline) in most patients. By comparison, specific antagonists to the ADH-V₂ (collecting tubule) receptor in the cortical collecting tubule have shown effectiveness, and two of these have been approved by the Food and Drug Administration (FDA) at the time of this writing.

Conivaptan, an antagonist to both the V₁ (vascular) and V₂ (ADH) receptors, was first approved. It must be given intravenously in the hospital and has the propensity to cause phlebitis. Recent data suggest that a single 20 mg bolus intravenously over 30 minutes results in a sustained water diuresis and may avoid vascular injury. It is not suitable for chronic use. Tolvaptan is an oral ADH antagonist which is specific for the V₂ receptor. It must also be initiated in the hospital but can be administered in the outpatient setting after that.

The choice of initial therapy in symptomatic patients is usually 3% saline, and this is the preferred treatment with severe neuropathology (such as seizures). Because there are no controlled prospective studies comparing hypertonic saline with the vaptans, it is difficult to recommend the latter in the SIADH as first-line agents, particularly when cost is considered. Recently, a European Consortium of three medical societies did not recommend the use of vaptans for acute symptomatic hyponatremia in the setting of SIADH or volume overload [19]. When they are administered, it is important to relax fluid restriction during the initial titration with these agents to avoid an excessive rise in the serum sodium concentration. Given the higher cost, liver function test abnormalities, and lack of proven benefit over conventional therapies (hypertonic saline), the role of vaptans is not well defined.

**Urea.** Oral urea has been used to treat hyponatremia and brain swelling since the 1980s. It is a hydrophilic compound that does not readily cross the blood–brain barrier and creates an osmotic gradient, thereby allowing water to flow out of the brain in a slower fashion that hypertonic...
saline. With normal kidney function, administered urea is excreted within 12 hours, which promotes the excretion of free water. Although not approved in the United States, its use has been recommended in Europe for the treatment of SIADH [20]. Correction of chronic hyponatremia in rats with the use of urea may be associated with fewer neurologic complication compared with hypertonic saline or lixivaptan [21].

Identification of a reset osmostat is important because the therapeutic recommendations for SIADH discussed here do not apply in this setting. These patients generally have mild, asymptomatic hyponatremia because of downward resetting of the threshold for both ADH release and thirst. Because osmoregulatory function is normal around the new baseline, attempting to raise the plasma sodium concentration increases ADH levels and makes the patient very thirsty, a response that is similar to that seen with water restriction in healthy subjects. Thus, efforts to raise the plasma sodium concentration are both unnecessary and likely to be ineffective. Treatment should be primarily directed at the underlying disease.

**Treatment of Hyponatremia in Edematous States.** Raising the plasma sodium concentration in patients with edema may be more difficult than in those conditions described earlier. Most of these individuals have advanced CHF or liver disease. Consequently, sodium administration is generally contraindicated.

**Congestive Heart Failure.** Restricting water intake is the mainstay of therapy in hyponatremic patients with heart failure, although this is often not tolerable because of the intense stimulation of thirst. The combination of an angiotensin-converting enzyme (ACE) inhibitor (or angiotensin receptor blocker [ARB]) and a loop diuretic may induce an elevation in the plasma sodium concentration [22,23]. Tolvaptan may be useful in some patients (see above), but must be initiated in the hospital. Tolvaptan has been approved for the treatment of hyponatremia in the setting of CHF as well as cirrhosis. However, there are no data on improvement in mortality versus conventional therapy [24]. In addition, the FDA in 2013 issued a warning about liver function abnormalities with the use of tolvaptan [25].

**Liver Disease.** Hyponatremia of patients with hepatic cirrhosis usually develops slowly and produces no cerebral edema or symptoms. It is possible, however, that a low plasma sodium concentration can exacerbate hepatic encephalopathy. In view of the marked sodium and water retention, the mainstay of therapy in this setting is restricting water intake to a level sufficient to induce negative water balance and partial correction of the hyponatremia. Hypertonic saline or salt tablets are
indicated only in patients with symptomatic hyponatremia. Diuretics can be given concurrently to prevent worsening of the edema, but overly rapid correction must be avoided to minimize the risk of central demyelinating lesions. As is the case with hyponatremic CHF patients, demeclocycline has been evaluated in this setting, but its use has been limited because of its nephrotoxicity [26].

Hypernatremia

Hypernatremia can be produced by the administration of hypertonic sodium solutions. However, in almost all cases, there is loss of free water. Persistent hypernatremia does not occur in healthy subjects because the ensuing rise in $P_{\text{Osm}}$ stimulates both thirst and the release of ADH, which minimizes further water loss. The associated increase in water intake then lowers the plasma sodium concentration to normal. This regulatory system is so efficient that the $P_{\text{Osm}}$ is maintained within a range of 1% to 2% despite wide variations in sodium and water intake. Even patients with diabetes insipidus, who often have marked polyuria because of diminished ADH effect, maintain a near-normal plasma sodium concentration by appropriately increasing water intake.

The result is that hypernatremia occurs primarily in those patients who cannot express thirst normally; most often, these patients are infants and adults with impaired mental status, and the elderly, who also appear to have diminished osmotic stimulation of thirst via an unknown mechanism. A patient with a plasma sodium concentration of 150 mEq per L or more who is alert but not thirsty has, by definition, a hypothalamic lesion (either structural or functional) affecting the thirst center.

Etiology of Hypernatremia

The major causes of hypernatremia are listed in Table 199.4.

Free Water Loss. The unreplaced loss of solute-free water leads to an elevation in the plasma sodium concentration. Because the plasma sodium concentration and $P_{\text{Osm}}$ are determined by the ratio of total body solutes (i.e., effective osmoles, chiefly sodium and potassium salts) to TBW, the amounts of sodium and potassium in a fluid determine how loss of that fluid affects body osmolality [2]. The composition of diarrheal fluid can be used to illustrate this point. Many viral and osmotic diarrheas are associated with an isosmotic diarrheal fluid that has a sodium plus potassium concentration between 40 and 100 mEq per L; organic solutes, which do not affect the plasma sodium concentration, make up the remaining osmoles. Loss of this fluid tends to induce hypernatremia because water is being lost in excess of sodium plus potassium. Similar considerations apply to urinary losses during an osmotic diuresis induced by glucose, mannitol, or urea. Patients with secretory diarrheas such as cholera excrete a diarrheal fluid with a sodium and potassium concentration similar to that of plasma. Loss of this fluid causes volume and potassium depletion but does not directly affect the plasma sodium concentration.

With these considerations in mind, the sources of free water loss that can lead to hypernatremia if intake is not increased include the following:

Insensible and sweat losses. Insensible water losses from the skin by evaporation and sweat are relatively dilute. The loss of this fluid is increased by fever, exercise, and exposure to high temperatures.

Gastrointestinal losses. As mentioned previously, most gastrointestinal losses promote the development of hypernatremia because the sodium plus potassium concentration is less than that in the plasma. An elevation in the plasma sodium concentration with a diarrheal illness is particularly common in infants.

Central or nephrogenic diabetes insipidus. Decreased release of ADH or renal resistance to its effect causes the excretion of relatively dilute urine. Most affected patients have a normal thirst mechanism and,
therefore, typically present with polyuria and polydipsia and a high-normal plasma sodium concentration. However, marked and symptomatic hypernatremia occurs if there is inadequate replacement (either oral or intravenous) of the urinary water losses. Central diabetes insipidus (CDI) is associated with deficient secretion of ADH. This condition is most often idiopathic (possibly as a result of autoimmune injury to the ADH-producing cells) or induced by trauma, pituitary surgery or infiltration, or hypoxic or ischemic encephalopathy. When CDI develops following trauma or surgery, a triphasic response may be observed [27]. In this condition, initial inhibition of ADH results in polyuria, followed by uncontrolled release of ADH from injured cells, and, subsequently, by permanent CDI.

Nephrogenic diabetes insipidus (NDI) is characterized by normal ADH secretion but varying degrees of renal resistance to its water-retaining effect. In its mild form, NDI is relatively common because most patients who are elderly or who have underlying renal disease have a reduction in maximum concentrating ability. This defect, however, is not severe enough to produce a symptomatic increase in urine output. True polyuria owing to ADH resistance occurs primarily in four settings: X-linked hereditary NDI in children in which there is an abnormality in the renal V2 receptors for ADH or in the ADH-sensitive water channel (aquaporin 2) [27], chronic lithium use, hypercalcemia, and severe hypokalemia.

Osmotic diuresis. An osmotic diuresis owing to glucose, mannitol, or urea causes an increase in urine output in which the sodium plus potassium concentration is well below that in the plasma because of the presence of the excreted organic solute. Patients with diabetic ketoacidosis or nonketotic hyperglycemia typically present with hyperosmolality, although the plasma sodium concentration may be kept normal or low by the hyperglycemia-induced water movement out of cells.

Hypothalamic lesions affecting thirst or osmoreceptor function. Hypernatremia can occur in the absence of increased water losses if there is a primary hypothalamic disease impairing thirst (called hypodipsia). In patients with this problem, forced water intake is usually sufficient to maintain a normal plasma sodium concentration, although CDI, if present, should be treated.

Other hypodipsic patients do not respond to water loading, because the excess water is excreted in the urine with little change in the plasma
sodium concentration. These patients have selective injury to the hypothalamic osmoreceptors, with ADH secretion being primarily governed by changes in blood volume (volume receptors remain intact). Thus, the suppression of ADH release by water loading in such patients is caused by the associated mild volume expansion rather than to a fall in $P_{\text{Osm}}$ [28]. This disorder was termed essential hypernatremia, but is now called adipsic diabetes insipidus. Correction is difficult, because ADH release and suppression is driven by volume and not by the serum osmolality.

True upward resetting of the osmostat has been described only in patients with primary mineralocorticoid excess (such as in primary hyperaldosteronism). Presumably, the suppressive effect of chronic mild volume expansion on ADH release is responsible for this phenomenon. The plasma sodium concentration in these patients is frequently between 141 and 145 mEq per L and may be a clue to the diagnosis.

**Water Loss into Cells.** Transient hypernatremia, in which the plasma sodium concentration can rise by 10 to 15 mEq per L within a few minutes, can be induced by intense exercise or seizures, activities that are also associated with lactic acidosis. In this setting, the intracellular breakdown of glycogen into smaller, more osmotically active molecules, such as lactate, can increase water uptake into cells. The plasma sodium concentration returns to normal within 5 to 15 minutes after the cessation of exertion.

**Sodium Overload.** Acute and often marked hypernatremia, with plasma sodium concentrations even higher than 175 mEq per L, can be induced by administration of hypertonic sodium-containing solutions. Examples include salt poisoning in infants and young children, infusion of hypertonic sodium bicarbonate to treat metabolic acidosis, and massive salt ingestion, such as can occur when a highly concentrated saline emetic or gargle is swallowed. This type of hypernatremia corrects spontaneously if renal function is normal, because the excess sodium is rapidly excreted in the urine. Even with optimal therapy, however, the mortality rate is extremely high in adults with a plasma sodium concentration that has suddenly risen to more than 180 mEq per L [29]; for reasons that are poorly understood, severe hypernatremia is often better tolerated in young children.

**Symptoms of Hypernatremia**

Hypernatremia is basically a mirror image of hyponatremia. The rise in the plasma sodium concentration and osmolality causes rapid water movement out of the brain; this decrease in brain volume can cause
tension, thereby leading to rupture of the cerebral veins with focal intracerebral and subarachnoid hemorrhages and possible irreversible neurologic damage. The clinical manifestations of this disorder begin with lethargy, weakness, and irritability and can progress to twitching, seizures, and coma. Severe symptoms usually require an acute elevation in the plasma sodium concentration to more than 158 mEq per L.

Despite the generalized reduction in cell volume with hypernatremia, brain volume is gradually restored because of both water movement from the cerebrospinal fluid into the brain (thereby increasing the interstitial volume) and to the uptake of solutes by the brain cells (thereby pulling water into the cells). The latter response involves an initial uptake of sodium and potassium salts, followed by the later accumulation of osmolytes such as inositol and the amino acids glutamine and glutamate [30]. The effect is that these osmolytes, which do not interfere with cell function, account for approximately 35% of the new cell solute.

As in hyponatremia, the cerebral adaptation in hypernatremia has two important clinical consequences:

1. Chronic hypernatremia is much less likely to induce neurologic symptoms. Assessment of symptoms attributable to hypernatremia is often difficult because most affected adults have underlying neurologic disease, which diminishes the protective thirst mechanism that normally prevents the development of hypernatremia, even in patients with diabetes insipidus.

2. Correction of chronic hypernatremia must occur slowly to prevent rapid fluid movement into the brain leading to cerebral edema, which can cause seizures and coma. Although the brain cells can rapidly lose potassium and sodium in response to this cell swelling, the loss of accumulated osmolytes occurs more slowly, a phenomenon that acts to hold water within the cells. The loss of inositol, for example, requires both a reduction in synthesis of new sodium–inositol cotransporters and the activation of a specific inositol efflux mechanism in the cell membrane. The delayed clearance of osmolytes from the cell can predispose to cerebral edema if the plasma sodium concentration is corrected too rapidly.

Diagnosis of Hypernatremia and Polyuric Disorders

The cause of the hypernatremia is usually evident from the history. When the cause is unclear, the correct diagnosis can usually be established by evaluation of the integrity of the ADH-renal axis via measurement of the $U_{Osm}$. A rise in the plasma sodium concentration is a potent stimulus to ADH release as well as to thirst; furthermore, a $P_{Osm}$ of more than 295
mOsm per kg (representing a plasma sodium concentration of approximately 145 to 147 mEq per L) generally leads to sufficient ADH secretion to maximally stimulate urinary concentration.

Thus, if both hypothalamic and renal functions are intact, the $U_{Osm}$ of a person with hypernatremia should exceed 700 to 800 mOsm per kg. In this setting, unreplaced insensible or gastrointestinal losses, sodium overload, or, rarely, a primary defect in thirst is likely to be responsible for the hypernatremia. Exogenous ADH does not produce a further rise in the $U_{Osm}$.

The chemical composition of the urine is diagnostically useful. The urinary sodium concentration should be less than 20 mEq per L when water loss and volume depletion are the primary problems, but it is typically well above 100 mEq per L in a salt-overload state. If the $U_{Osm}$ is significantly lower than that of the hyperosmolar plasma, then either central (ADH-deficient) or nephrogenic (ADH-resistant) diabetes insipidus is present.

**Diagnosis of Polyuric States and Diabetes Insipidus.** Polyuria can be arbitrarily defined as urine output exceeding 3 L per day. It must be differentiated from the more common complaints of frequency and nocturia, which are usually not associated with an increase in the total urine output. Excluding osmotic diuresis from uncontrolled diabetes mellitus, polyuria in the outpatient setting is typically caused by primary polydipsia, CDI, or NDI.

These conditions are all associated with an increase in urine output and the excretion of relatively dilute urine. With primary polydipsia, the polyuria is an appropriate response to excessive water intake and is not associated with hypernatremia. In comparison, the water loss is inappropriate with either form of diabetes insipidus. Thus, a low plasma sodium concentration at presentation (<137 mEq per L) owing to water overload is usually indicative of primary polydipsia, whereas a high-normal plasma sodium concentration (>142 mEq per L) points toward diabetes insipidus. Marked hypernatremia is uncommon in diabetes insipidus because loss of water stimulates the thirst mechanism, resulting in an increase in intake to match the urinary losses. An exception to this general rule is the patient with a central lesion impairing both ADH release and thirst.

The correct diagnosis is often inferred from the plasma sodium concentration and from the history. The patient should be questioned about the causes of CDI or NDI and about the rate of onset of the polyuria; the polyuria is usually abrupt in CDI (“I suddenly began urinating excessively 2 days ago”) but gradual in NDI or primary polydipsia. Testing the kidneys’ ability to concentrate the urine in
response to a high $P_{Osm}$ can confirm the diagnosis. The $P_{Osm}$ can be raised either by water restriction or, less commonly, by the administration of hypertonic saline (0.05 mL/kg/min for no more than 2 hours). These maneuvers are unnecessary if the patient’s $P_{Osm}$ is already at or above 295 mOsm per kg because endogenous ADH effect on the kidneys should be maximal.

The water restriction test for the evaluation of polyuria involves measurement of the urine volume and osmolality every hour and plasma sodium concentration and $P_{Osm}$ every 2 hours. The patient should stop drinking 2 to 3 hours before beginning the test; overnight fluid restriction should be avoided because potentially severe volume depletion and hypernatremia can occur in patients with marked polyuria.

The water restriction test is continued until the $U_{Osm}$ reaches a clearly appropriate level of concentration (approximately 600 mOsm per kg, indicating that both ADH release and effect are intact), the $U_{Osm}$ is stable on two or three successive measurements despite a rising $P_{Osm}$, more than 3% to 5% of body weight is lost, or the $P_{Osm}$ exceeds 295 to 300 mOsm per kg. If urinary concentration is inadequate, exogenous ADH is then given, usually in the form of 10 μg of deamino-8-D-arginine vasopressin [DDAVP; also called desmopressin] by nasal insufflation, and the $U_{Osm}$ and volume are monitored over every 30 minutes for 90 minutes. Measuring the serum ADH level at the start of the test and immediately before DDAVP is administered may be useful.

Each of the causes of polyuria produces a distinct pattern as depicted in Figure 199.3:

1. CDI is usually partial and, therefore, associated with a rise in the $U_{Osm}$ as the $P_{Osm}$ increases. The degree of urinary concentration is clearly submaximal, however; and because ADH release is inadequate, exogenous ADH leads to a rise in the $U_{Osm}$ of 15% to 50% and a corresponding fall in urine output.

2. NDI is also associated with a submaximal rise in $U_{Osm}$, but there is no urinary response to exogenous ADH. It must be emphasized that NDI is a rare cause of true polyuria in adults in the absence of lithium use, hypercalcemia, hypokalemia, or, rarely, renal tubular disease.
Primary polydipsia is associated with a rise in $U_{\text{Osm}}$, usually to more than 500 mOsm per kg, and no response to exogenous ADH because endogenous release is intact. The chronic polyuria in this disorder can partially wash out the medullary interstitial solute gradient; as a result, maximal concentrating ability is impaired, and the $U_{\text{Osm}}$ may only reach 500 to 600 mOsm per kg, as compared with 800 mOsm per kg or more in healthy subjects.

**FIGURE 199.3** Response to antidiuretic hormone (ADH) after a water restriction test. ADH is given when the osmolality of plasma ($P_{\text{Osm}}$) reaches 295 mOsm per kg, the level at which maximal ADH release and response should be present. This test identifies the cause of polyuria in approximately 80% of patients. Confusion may arise, however, with partial diabetes insipidus (CDI). In this disorder, some individuals have lower than normal ADH levels at a normal $P_{\text{Osm}}$, but the increase in ADH (although still subnormal) generates a maximum urine response, presumably because of increased sensitivity. Consequently, these patients exhibit polyuria at a normal $P_{\text{Osm}}$, but the curve during the water restriction test may mimic partial nephrogenic diabetes insipidus (NDI) or primary polydipsia. Measurement of plasma ADH levels may be needed to distinguish these possibilities.

There is, however, one major potential source of error. Patients with partial CDI may be hyperresponsive to the submaximal rise in ADH
induced by water restriction, perhaps because of receptor upregulation. As a result, they may be polyuric at the normal $P_{Osm}$ of 285 to 290 mOsm per kg when ADH levels are very low, but they may have a maximally concentrated urine at a $P_{Osm}$ of more than 295 mOsm per kg when ADH levels are somewhat higher. In such patients, exogenous ADH is without effect, resulting in a pattern suggestive of primary polydipsia or NDI. Therefore, measurement of plasma ADH levels may be useful.

In some polyuric patients, the increase in urine output is because of a solute or an osmotic diuresis in which decreased solute reabsorption is the primary abnormality. Although glucosuria is the most common cause of osmotic diuresis in outpatients, other conditions may account for some cases. These include high-protein feedings (in which urea acts as the osmotic agent) and volume expansion owing to saline loading or the administration of mannitol. The $U_{Osm}$ in these disorders is usually greater than 300 mOsm per kg, in contrast to the dilute urine typically found with a water diuresis. Total solute excretion, which is calculated from the product of the $U_{Osm}$ and volume of a 24-hour urine sample, is normal with a water diuresis (600 to 900 mOsm per day) but markedly increased with an osmotic diuresis.

Although renal disease can impair sodium conservation in the presence of volume depletion, it rarely causes sufficient sodium wasting to induce true polyuria. For example, the polyuria of postobstructive diuresis is caused by renal excretion of excess fluid and solute, not water and solute wasting. Although urine output may initially exceed 1,000 mL per hour, optimal therapy consists of fluid infusion at a maintenance level, such as 75 mL of one-half isotonic saline per hour. The development of volume depletion, as evidenced by hypotension or a rise in the BUN, is unusual with this regimen.

**Treatment of Hypernatremia**

The water deficit of a hypernatremic patient can be estimated from the following calculation. The quantity of osmoles in the body is equal to the osmolar space (the TBW) times the osmolality of the body fluids:

$$\text{Total body osmoles} = \text{TBW} \times P_{Osm}$$

$$\text{Water deficit} = \text{current body water (plasma Na}^+ / 140 - 1]\text{) }$$

where current (observed) body water = 60% body mass.

This formula estimates the amount of positive water balance required to return the plasma sodium concentration to 140 mEq per L. It does not account for electrolyte losses that may occur conjointly with water losses in such settings as osmotic diuresis or diarrhea.
Rate of Correction. As in hyponatremia, overly rapid correction is potentially dangerous in chronic hypernatremia (present for >48 hours). Rapidly lowering the plasma sodium concentration once osmotic adaptation has occurred may cause cerebral edema and lead to seizures, permanent neurologic damage, or death. This adverse sequence has been described in children in whom hypernatremia was corrected at a rate exceeding 0.7 mEq/L/h. In comparison, no neurologic sequelae were induced when the plasma sodium concentration was lowered at 0.5 mEq/L/h [31]. However, in elderly patients, slow correction (<0.25 mEq/L/h) is associated with increased mortality [32]. Similar to treatment of hyponatremia, the plasma sodium concentration should not be corrected by more than 8 to 10 mEq per L over 24 hours. In contrast, acute hypernatremia should be rapidly corrected over 24 to 48 hours.

The water deficit represents the existing amount of water loss that must be offset; ongoing free water losses, including insensible losses (approximately 40 mL per hour), must also be replaced. The replacement fluid can be administered orally or intravenously as dextrose in water. Sodium or potassium can be added if there are concurrent losses of these cations, but the addition of these solutes decreases the amount of free water that is being given. It should be emphasized that an isotonic saline solution should be used as initial therapy in the volume-depleted, hypotensive patient because restoration of tissue perfusion is of primary importance.

Treatment of Diabetes Insipidus. The major symptoms of both forms of diabetes insipidus are polyuria and polydipsia. Treatment for these disorders is aimed at decreasing the urine output.

Central Diabetes Insipidus. Because the primary problem is deficient secretion of ADH, control of the polyuria can be achieved by hormone replacement using DDAVP (desmopressin), a two–amino acid synthetic analogue of ADH. DDAVP is administered by nasal spray in a usual dose starting at 5 μg once a day. Because nocturia is often the most troubling symptom, the initial dose is usually given at night. Tablets of desmopressin are also available although their absorption may vary in different patients. Therefore, switching from the intranasal form to a tablet may require titration and close monitoring. The starting dose of the tablet is 0.05 mg per day. The size and necessity for a daytime dose can be determined by the effectiveness of the evening dose. If, for example, polyuria does not recur until noon, then one-half of the evening
doses may be sufficient at that time.

One important potential risk inherent in treating CDI with DDAVP is that of water retention leading to the development of hyponatremia. There are several reasons why this may occur. Patients are no longer polyuric once on therapy. Because they are on a fixed dose of DDAVP, their ADH activity is constant and not regulated. V$_2$ receptors may be upregulated as a result of prolonged deprivation of vasopressin. Finally, some patients may retain their habitually large consumption of water even after their polyuria ceases. Hyponatremia in this context can be avoided by giving the minimum dose that is required to control the polyuria.

**Nephrogenic Diabetes Insipidus.** NDI results from partial or complete resistance of the kidney to the effects of ADH. As a result, patients with this disorder are not likely to respond to DDAVP.

In adults, a concentrating defect severe enough to produce polyuria as a result of NDI is most often because of chronic lithium use or hypercalcemia. Less frequently, it is caused by other conditions that impair tubular function, such as Sjögren’s syndrome. Therapy targets correction of the underlying disorder or discontinuing a causative drug. In hypercalcemic patients, for example, normalization of the plasma calcium concentration usually leads to amelioration of polyuria. In contrast, lithium-induced NDI may be irreversible if the patient already has severe tubular injury and a marked concentrating defect.

Thiazide diuretics can diminish the degree of polyuria in patients with persistent and symptomatic NDI. The combination of a low-sodium diet with a thiazide diuretic (such as hydrochlorothiazide, 25 mg once or twice daily) acts by inducing mild volume depletion. As little as a 1.0- to 1.5-kg weight loss can reduce the urine output by more than 50%, presumably mediated by a hypovolemia-induced increase in proximal sodium and water reabsorption, with diminished water delivery to the ADH-sensitive sites in the collecting tubule.

Thiazide diuretics also limit the ability to dilute the urine. As a result, the concentration of urine in a thiazide-treated individual with NDI typically increases, even in the absence of ADH. This contributes to the decrease in urine volume. As an example, in a patient with a normal solute excretion rate of 900 mOsm/kg/day and a maximum $U_{Osm}$ of 150 mOsm per kg as a result of NDI, a urine output of at least 6 L per day is expected (900 ÷ 150). In contrast, if a thiazide diuretic limits the minimum $U_{Osm}$ to 300 mOsm per day, daily urine output decreases to approximately 3 L each day (900/300).

Thiazide-induced natriuresis can be enhanced by combination therapy with amiloride (or another potassium-sparing diuretic). This regimen has
an additional benefit in that amiloride partially blocks the potassium wasting induced by the thiazide. The efficacy of amiloride in patients with reversible lithium nephrotoxicity is directly related to its site and mechanism of action [33]. This drug closes the sodium channels in the luminal membrane of the collecting tubule cells. These channels constitute the mechanism by which filtered lithium normally enters these cells and then interferes with their response to ADH. In contrast to amiloride, thiazide diuretics should be used cautiously, if at all, in patients with lithium-induced NDI who are still taking lithium because volume depletion can lead to increased proximal lithium reabsorption and potentially toxic plasma lithium levels.

Nonsteroidal anti-inflammatory drugs (NSAIDs) cause inhibition of renal prostaglandin synthesis. This has the effect of increasing concentrating ability because prostaglandins normally antagonize the urinary concentrating action of ADH. If, for example, healthy subjects are given a submaximal dose of ADH, the ensuing rise in $U_{Osm}$ can be increased by more than 200 mOsm per kg if the patient has been pretreated with an NSAID. The result in patients with NDI may be a 25% to 50% reduction in urine output, a response that is partially additive to that of a thiazide diuretic. Not all NSAIDs are equally effective in a given patient. For example, some patients may have a good response to indomethacin but derive little, if any, benefit from ibuprofen. The impact of cyclooxygenase-2 inhibitors remains to be determined. However, these agents can exacerbate CHF and have been associated with fluid overload, in a manner similar to that of nonselective NSAIDs [34].

Dietary modification via the use of a low-sodium, low-protein diet can diminish the urine output in patients with NDI. The resultant decrease in net solute excretion (as sodium salts and urea) at any given $U_{Osm}$ reduces the urine output. Most patients with NDI have partial, rather than complete, resistance to ADH. It is, therefore, possible that administering exogenous ADH in doses sufficient to achieve supraphysiologic hormone levels can increase the renal effect of ADH.

---

1The molecular weights of glucose and nitrogen are 180 and 14, respectively. As a result, the osmotic effect of glucose is determined by dividing by 18 (because the concentration is in 100 mL of plasma and not 1 L), whereas that of BUN is obtained by dividing by 2.8 (there are two nitrogens on each molecule of urea).
DISORDERS OF PLASMA POTASSIUM

Potassium is the major intracellular cation. Only approximately 2% of body potassium is located in the extracellular space, where the concentration (3.5 to 5.0 mEq per L) is much lower than inside cells (125 to 140 mEq per L). This concentration difference is preserved by the Na⁺/K⁺-adenosine triphosphatase (ATPase) pump that actively transports sodium out of, and potassium into, most cells. Because such a small proportion of K⁺ is extracellular, even a slight change in plasma potassium concentration can engender dramatic effects on myoneural cell physiology.

Normal Potassium Homeostasis

Daily potassium intake in the United States varies between 40 and 120 mEq. Most of this (approximately 90%) is eliminated by the kidney; the rest is excreted in stool. In chronic kidney disease, gastrointestinal potassium excretion increases, a process that depends, in part, on aldosterone.

Only approximately 50% of potassium ingested in the diet or administered parenterally appears in the urine during the first 4 hours. Consequently, more than half of an acute potassium load must be rapidly translocated into cells if life-threatening hyperkalemia to be averted.

Transcellular Potassium Shifts

The most important factors involved in transporting K⁺ intracellularly are insulin and β-adrenergic stimulation. Insulin stimulates the Na⁺/K⁺-ATPase pump present in most cell membranes, accelerating the transfer process.

Activation of β-adrenergic receptors (specifically the β₂-receptor) also stimulates K⁺ movement from the plasma into cells. The pathophysiology is, in part, owing to direct stimulation of the Na⁺/K⁺-ATPase pump. The observation that the hypokalemic effect of terbutaline (a β-adrenergic agonist) can be blunted by somatostatin suggests that insulin may have a mediatory role in the hypokalemic response to β-adrenergic stimulation.

Aldosterone is the principal hormone stimulating K⁺ secretion by the
renal tubule. This effect is important in all epithelial cell surfaces.

Renal Regulation of Potassium Excretion

Potassium is freely filtered at the glomerulus so that the concentration of K⁺ entering the early proximal tubule is approximately 4 mEq per L. Ninety percent of the filtered potassium load has been reabsorbed by the time the glomerular filtrate reaches the distal tubule. Most renal K⁺ excretion normally occurs as a result of secretion by the distal nephron. Potassium secretion occurs in the principal cells of the cortical collecting tubule (Fig. 199.4). Movement of potassium from the tubular cell into the lumen is controlled by the existing state of potassium balance, the rate of sodium reabsorption (a process driven by aldosterone) that generates a lumen-negative electrical gradient down which K⁺ can move, and the rate of distal urine flow that maintains a high tubular cell-to-lumen potassium gradient by washing away secreted K⁺.

**FIGURE 199.4** Schematic representation of sodium and potassium transport mechanisms in the sodium-reabsorbing cells in the collecting tubules. The entry of filtered sodium into the cells is mediated by selective sodium channels in the apical (luminal) membrane; the energy for this process is provided by the favorable electrochemical gradient for sodium (cell interior electronegative and low cell sodium concentration). Reabsorbed sodium is pumped out of the cell by the Na⁺/K⁺-adenosine triphosphatase (ATPase) pump in the basolateral (peritubular) membrane. The reabsorption of cationic sodium makes the lumen electronegative, thereby creating a favorable gradient for the secretion of potassium into the lumen via potassium channels in the apical membrane. Aldosterone (Aldo), after combining with the cytosolic mineralocorticoid receptor (Aldo-R), leads to enhanced sodium reabsorption and
potassium secretion in the cortical collecting tubule by increasing both the number of open sodium channels and the number of Na\(^+\)/K\(^+\)–ATPase pumps. Atrial natriuretic peptide (ANP), on the contrary, acts primarily in the inner medullary collecting duct by combining with its basolateral membrane receptor (ANP-R) and activating guanylate cyclase. ANP inhibits sodium reabsorption by closing the sodium channels. The potassium-sparing diuretics amiloride and triamterene act by closing the sodium channels directly, and spironolactone acts by competing with aldosterone for binding to the mineralocorticoid receptor.

Aldosterone enters the principal cell from the basolateral (antiluminal) side. Once inside, it binds to receptors, which increase the number of open luminal sodium channels and increase the number and activity of the Na\(^+\)/K\(^+\)-ATPase pumps in the basolateral membrane. The ensuing increase in cell potassium favors the secretion of K\(^+\) into the lumen, down the electrochemical gradient provided by Na\(^+\) reabsorption.

In states of potassium depletion, potassium secretion in the cortical collecting tubule is reduced, and potassium reabsorption stimulated. Reabsorption takes place in the intercalated (acid-secreting) cells of this nephron segment (Fig. 199.5).

**FIGURE 199.5** Transport mechanisms involved in hydrogen secretion and bicarbonate and potassium reabsorption in type-A intercalated cells in the cortical collecting tubule and in the outer medullary collecting tubule cells. Water (H\(_2\)O) within the cell dissociates into hydrogen and hydroxyl anions. The former are secreted into the lumen by H–adenosine triphosphatase (ATPase) pumps in the luminal membrane; chloride may be cosecreted with hydrogen to maintain electroneutrality. The hydroxyl anions in the cell combine with carbon dioxide to form bicarbonate in a reaction catalyzed by carbonic...
anhydrase (CA). Bicarbonate is then returned to the systemic circulation via chloride–bicarbonate exchangers in the basolateral membrane. The favorable inward concentration gradient for chloride (plasma and interstitial concentration greater than that in the cell) provides the energy for bicarbonate reabsorption. H/K-ATPase pumps, which lead to both hydrogen secretion and potassium reabsorption, may also be present in the luminal membrane. The number of these pumps increases with potassium depletion, suggesting that their main function is to promote potassium conservation.

**Hypokalemia**

Potassium entering the body is largely stored in the cells and then excreted in the urine. Thus, a reduction in the plasma potassium concentration can result from decreased intake, increased cellular uptake, or increased losses. These losses, which are the most common contributors to hypokalemia, can occur via the urine, the gastrointestinal tract, or, less commonly, through the skin (Table 199.5).

Causes of Hypokalemia

**Decreased Potassium Intake.** Because the kidney can lower potassium excretion to less than 25 mEq per day in response to potassium depletion, decreased intake alone rarely causes hypokalemia, but it can enhance the severity of other causes of potassium depletion such as diuretic therapy.

**Increased Entry into Cells.** The markedly inequitable distribution of potassium between the cells and the extracellular fluid is maintained by the Na⁺/K⁺-ATPase pump in the cell membrane. Occasionally, increased potassium entry into cells may result in transient hypokalemia.

**Elevation in Extracellular pH.** The transcellular hydrogen ion shifts accompanying metabolic and respiratory alkalosis obligate increased sequestration of potassium in cells. In general, this direct effect is relatively small because the plasma potassium concentration falls to less than 0.4 mEq per L for every 0.1-unit rise in pH. This phenomenon provides the rationale for the administration of sodium bicarbonate to treat the hyperkalemia of metabolic acidosis.

Despite the fact that the direct effect of alkalemia is relatively small, hypokalemia is common in metabolic alkalosis. The major reason for this association is that the underlying cause (diuretics, vomiting, or hyperaldosteronism) leads to losses of both hydrogen and potassium ions.

**Increased Availability of Insulin.** Insulin promotes the entry of potassium into skeletal muscle and hepatic cells by increasing the activity of the Na⁺/K⁺-ATPase pump in the cell membrane. This effect is most prominent after the administration of insulin to patients with diabetic ketoacidosis or severe nonketotic hyperglycemia.

The plasma potassium concentration can also be reduced in nondiabetic patients by a carbohydrate load. Thus, intravenous administration of potassium chloride in a dextrose-containing solution in an effort to correct hypokalemia can transiently further reduce the
plasma potassium concentration and, possibly, lead to cardiac arrhythmias.

**Elevated β-Adrenergic Activity.** Catecholamines, acting via β₂-adrenergic receptors, promote potassium entry into the cells by increasing Na⁺/K⁺-ATPase activity. As a result, transient hypokalemia can occur with stress-induced release of epinephrine, as in acute illness, coronary ischemia, theophylline intoxication, or alcohol withdrawal. A similar effect, in which the plasma potassium concentration can fall acutely by more than 0.5 to 1.0 mEq per L, can be achieved by the administration of a β-adrenergic agonist (such as albuterol, terbutaline, or epinephrine). This effect must be considered when diuretic therapy is used for the treatment of hypertension in patients receiving β-agonists for asthma or chronic lung disease. The hypokalemic response to epinephrine can be blocked by a nonselective β-blocker (such as propranolol), but a β₁-selective agent (such as atenolol) offers no protection, at least at lower doses (<100 mg per day).

---

**Hypokalemic Periodic Paralysis.** Hypokalemic periodic paralysis is a rare disorder of uncertain cause characterized by potentially fatal episodes of muscle weakness or paralysis that can affect the respiratory muscles. Acute attacks—in which the sudden movement of potassium into the cells can lower the plasma potassium concentration to as low as 1.5 to 2.5 mEq per L—are often precipitated by rest after exercise, stress, or a carbohydrate meal, events that are often associated with increased release of epinephrine or insulin. Hypokalemic periodic paralysis may be familial with autosomal dominant inheritance, or it may be acquired in patients (often, but not exclusively, Asian men) with thyrotoxicosis.

Oral administration of 60 to 120 mEq of potassium chloride usually aborts acute attacks within 15 to 20 minutes. Another 60 mEq can be given if no improvement is noted. The presence of hypokalemia must be confirmed before therapy because potassium can worsen episodes caused by the normokalemic or hyperkalemic forms of periodic paralysis. Furthermore, excess potassium administration during an acute episode may lead to posttreatment hyperkalemia as potassium moves back out of the cells.

**Marked Increase in Blood Cell Production.** An acute increase in hematopoietic cell production is associated with potassium uptake by the new cells and possible hypokalemia. This most often occurs after the
administration of vitamin B_{12} or folic acid to treat a megaloblastic anemia or of granulocyte-macrophage colony-stimulating factor to treat neutropenia.

Metabolically active blood cells may continue to absorb potassium after blood has been drawn. This phenomenon has been described in patients with acute myeloid leukemia and a high white blood cell count. In these patients, the measured plasma potassium concentration may be less than 1 mEq per L (without symptoms) if the blood is allowed to stand at room temperature for a prolonged period before separation of the plasma from the cells.

**Hypothermia.** Accidental or induced hypothermia (as occurs during cardiac bypass) can accelerate potassium movement into the cells and lower the plasma potassium concentration to less than 3.0 mEq per L. In contrast, hyperkalemia in an individual with severe hypothermia usually signifies irreversible tissue necrosis.

**Medications/Toxins.** Barium sulfide, used in pesticides, radiologic imaging, and depilatory agents, has been reported to cause severe transient hypokalemia when ingested [35]. Hypokalemia is a complication of severe chloroquine overdose [36].

**Increased Gastrointestinal Losses.** Loss of gastric or intestinal secretions from any cause (vomiting, diarrhea, laxatives, or tube drainage) is associated with potassium wasting and, possibly, hypokalemia. However, it should be emphasized that the concentration of potassium in gastric secretions is relatively low (5 to 10 mEq per L) and that the potassium depletion is primarily because of increased urinary losses. The metabolic alkalosis that results from loss of gastric secretions raises the plasma bicarbonate concentration and, therefore, the filtered bicarbonate load above its proximal tubular reabsorptive threshold. More sodium bicarbonate and water are thus delivered to the distal potassium secretory site in the presence of hypovolemia-induced aldosterone release. Secreted potassium combines with the negatively charged bicarbonate and is excreted in the final urine, leading to hypokalemia.

The urinary potassium wasting seen with loss of gastric secretions is typically most prominent in the first few days; thereafter, proximal bicarbonate reabsorptive capacity increases, leading to a marked reduction in urinary sodium, bicarbonate, and potassium excretion. At this time, the urine pH falls from more than 7.0 to less than 5.5.

**Increased Urinary Losses.** Urinary potassium excretion is mostly derived from potassium secretion in the distal nephron, particularly by the principal cells in the cortical collecting tubule. This process is
primarily influenced by two factors: aldosterone and the distal delivery of sodium and water. Urinary potassium wasting generally requires increases in aldosterone or in distal flow. Aldosterone acts partly by stimulating sodium reabsorption. The removal of cationic sodium makes the lumen relatively electronegative, thereby promoting passive potassium secretion from the tubular cell into the lumen through specific potassium channels in the luminal membrane.

**Diuretics.** Any diuretic that acts proximal to the potassium secretory site, including carbonic anhydrase inhibitors and loop and thiazide diuretics, increases distal delivery and, via the induction of volume depletion, activates the renin–angiotensin–aldosterone system. As a result, urinary potassium excretion increases, potentially leading to hypokalemia.

**Primary Mineralocorticoid Excess.** Urinary potassium wasting is characteristic of any condition associated with primary hypersecretion of a mineralocorticoid, as occurs with an aldosterone-producing adrenal adenoma. Affected patients are usually hypertensive, and the differential diagnosis includes diuretic therapy (which may be surreptitious) in a patient with underlying hypertension and renovascular disease, in which increased secretion of renin leads to enhanced aldosterone release. By comparison, plasma renin activity is suppressed in primary states of mineralocorticoid excess.

**Nonreabsorbable Anions.** The presence of nonreabsorbable anions in the filtrate draws increased amounts of sodium to the distal nephron where it is reabsorbed at the expense of potassium. Examples of nonreabsorbable anions include bicarbonate in vomiting-induced metabolic alkalosis, β-hydroxybutyrate in diabetic ketoacidosis, hippurate in toluene exposure (glue sniffing), and penicillin in patients receiving high-dose penicillin therapy. The effect of nonreabsorbable anions is augmented when there is concurrent volume depletion. Both the resulting decrease in distal chloride delivery (limiting the ability of chloride reabsorption to dissipate the lumen-negative gradient) and the enhanced secretion of aldosterone promote potassium secretion.

**Metabolic Acidosis.** Increased urinary potassium losses can occur in several forms of metabolic acidosis by mechanisms similar to those already described. In diabetic ketoacidosis, for example, increased distal sodium and water delivery (because of the glucose-induced osmotic diuresis), hypovolemia-induced hyperaldosteronism, and β-hydroxybutyrate acting as a nonreabsorbable anion all can contribute to potassium wasting. Potassium wasting can also occur in both type-1 (distal) and type-2 (proximal) renal tubular acidosis (RTA) (see Chapter
Hypomagnesemia. Hypomagnesemia is present in up to 40% of patients with hypokalemia. In many cases, such as with diuretic therapy, vomiting, or diarrhea, there are concurrent potassium and magnesium losses. Hypomagnesemia of any cause can lead to increased urinary potassium losses. A direct effect of magnesium on tubular potassium transport is likely the mechanism by which hypomagnesemia promotes kaliuresis [37]. Diagnosis of concomitant hypomagnesemia is particularly important because the hypokalemia often cannot be corrected until the magnesium deficit is repaired.

Salt-Wasting Nephropathies. Occasionally, renal diseases associated with decreased proximal, loop, or distal sodium reabsorption can lead to hypokalemia via a mechanism similar to that induced by diuretics. This problem may arise in patients with Bartter’s syndrome or Gitelman’s syndrome, tubulointerstitial diseases, such as interstitial nephritis as a result of Sjögren’s syndrome or lupus, hypercalcemia, and tubular injury induced by lysozyme in patients with acute monocytic or myelomonocytic leukemia. Increased potassium uptake by the leukemic cells may also contribute to the fall in the plasma potassium concentration.

Polyuria. In the presence of potassium depletion, healthy subjects can lower their urinary potassium concentration to 5 to 10 mEq per L. If, however, the urine output is greater than 5 to 10 L per day, obligatory potassium losses can exceed to 50 to 100 mEq in this period. This problem is most likely to occur in primary polydipsia, in which the urine output may be elevated during a prolonged period. An equivalent degree of polyuria can also occur in CDI, but patients with this disorder typically seek medical care soon after the polyuria has begun.

Transcutaneous Losses. Daily potassium loss through the skin is normally negligible because the volume of perspiration is low and the potassium concentration is only 5 to 10 mEq per L. However, subjects exercising in a hot climate can produce 10 L or more of sweat per day, leading to potassium depletion if these losses are not replaced. Urinary potassium excretion may also contribute because aldosterone release is enhanced by both exercise (via catecholamine-induced renin secretion) and volume loss.

Extensive burns are another situation in which potassium losses through the skin may cause hypokalemia. Although the concentration of
potassium in sweat is low, the potassium concentration of fluid lost through the skin after burns may greatly exceed the plasma level because of local tissue breakdown, which leads to the release of potassium from cells.

**Dialysis.** Although patients with end-stage renal disease typically retain potassium and tend to be mildly hyperkalemic, hypokalemia can be induced in some patients by maintenance dialysis. This is more likely to occur in patients on chronic peritoneal dialysis, in whom dialysis is performed every day. By comparison, hemodialysis treatments are typically administered only three times per week. Nevertheless, transient hypokalemia often follows a hemodialysis treatment.

**Clinical Manifestations**

Most individuals with mild hypokalemia exhibit no symptoms referable to the low plasma K\(^+\) concentration. The major disturbances seen with more severe K\(^+\) deficiency are changes in cardiovascular, neuromuscular, and renal function. Cardiac toxicity may be manifested by serious arrhythmias because of hyperpolarization of the myocardial cell membrane, leading to a prolonged refractory period and increased susceptibility to reentrant arrhythmias. Earlier electrocardiographic (ECG) changes of hypokalemia include T-wave depression with prominent U waves (Fig. 199.6).

**FIGURE 199.6** Both hypokalemia and hyperkalemia can cause changes in the patient's electrocardiogram. The electrocardiogram from a patient with moderate hypokalemia shows prominent U waves.

Hyperpolarization also slows down nerve conduction and muscle contractions, which may contribute to symptoms such as muscle weakness, cramps, and paresthesias, although these are usually not observed until the plasma K\(^+\) concentration is less than 2.5 mEq per L. Severe hypokalemia may promote rhabdomyolysis. Profound hypokalemia can also impair respiratory muscle function, leading to hypoventilation.
Polyuria caused by stimulation of thirst and resistance to the action of ADH are the primary renal manifestations of hypokalemia. Increased thirst results from direct stimulation of the hypothalamic thirst center as well as from an appropriate response to polyuria. The mechanism of resistance to ADH appears to be because of reduced expression of the water channel (aquaporin-2).

**Diagnosis**

The cause of hypokalemia can usually be determined from the history. In some cases, the diagnosis is not readily apparent. The surreptitious vomiting of bulimia or the diarrhea of laxative abuse may be omitted from the patient’s history. Measurement of blood pressure and urinary potassium excretion and assessment of acid–base balance are often helpful in such cases.

**Urinary Potassium.** In the presence of potassium depletion, a healthy subject should lower urinary potassium excretion to less than 30 mEq per day; values above this level reflect at least a contribution from urinary potassium wasting. Random measurement of the urine potassium concentration can be used but is less accurate than a 24-hour collection. Extrarenal losses probably are present if the urine potassium concentration is less than 15 mEq per L, unless the patient is markedly polyuric. Higher values do not necessarily indicate potassium wasting if the urine volume is reduced. The response to potassium depletion is twofold: decreased potassium secretion by the collecting tubule principal cells and increased active potassium reabsorption by H/K-ATPase pumps in the luminal membrane of the adjacent type-A intercalated cells (Fig. 199.5). These pumps, which are activated by hypokalemia, reabsorb potassium and secrete hydrogen.

Once urinary potassium excretion is measured, the following diagnostic possibilities should be considered in the patient with hypokalemia of uncertain origin:

- Metabolic acidosis with a low rate of renal potassium excretion is suggestive of lower gastrointestinal losses as a result of diarrhea, laxative abuse, or a villous adenoma.
- Metabolic acidosis with renal potassium wasting is most often caused by diabetic ketoacidosis or by type-1 (distal) or type-2 (proximal) RTA. A salt-wasting nephropathy can produce similar findings, with the associated renal insufficiency responsible for the acidemia.
- Metabolic alkalosis with a low rate of urinary potassium excretion may be as a result of surreptitious vomiting or diuretic use if the urinary
collection is obtained several days after the vomiting or diuretic use has been halted.

Metabolic alkalosis with renal potassium wasting and a normal blood pressure most often results from ongoing vomiting, diuretic use, or, far less commonly, from Bartter’s syndrome or Gitelman’s syndrome. A low urine chloride concentration helps to distinguish the hypokalemia of vomiting from that of diuretics or Bartter’s syndrome and Gitelman’s syndrome.

Metabolic alkalosis with potassium wasting and hypertension suggests surreptitious diuretic therapy in patients with underlying hypertension, renovascular disease, or one of the causes of primary mineralocorticoid excess.

The possible presence of primary mineralocorticoid excess (with aldosterone and, to a lesser degree, deoxycorticosterone being the major endogenous mineralocorticoids) should be suspected in any patient with hypertension and unexplained hypokalemia and metabolic alkalosis.

The ingestion of licorice can produce a similar clinical and metabolic picture. The active compound in licorice, glycyrrhizic acid, inhibits renal 11β-hydroxysteroid dehydrogenase activity. This enzyme normally inactivates cortisol. The result is cortisol-induced stimulation of the mineralocorticoid receptor, leading to renal sodium retention and potassium loss.

The other major cause of hypertension and hypokalemia is renovascular disease, in which the hypersecretion of renin leads sequentially to increased secretion of angiotensin II and then aldosterone. It is important to be aware that hypokalemia is characteristic of malignant hypertension, which is a high renin, high aldosterone state, regardless of the underlying cause.

Treatment

Although hypokalemia can be transiently induced by the entry of potassium into the cells, most cases are caused by gastrointestinal or urinary losses. Optimal therapy depends on the severity of the potassium deficit; somewhat different considerations are required to minimize continued urinary losses caused by diuretic therapy or, less often, to one of the causes of primary hyperaldosteronism.
**Potassium Deficit.** The total potassium deficit can only be approximated because there is no strict correlation between the plasma potassium concentration and total body potassium stores. In general, the loss of 200 to 400 mEq of potassium is required to lower the plasma potassium concentration from 4 to 3 mEq per L; the loss of an additional 200 to 400 mEq lowers the plasma potassium concentration to approximately 2 mEq per L. Continued potassium losses do not as readily worsen the degree of hypokalemia because of the release of potassium from the intracellular pool.

These estimates assume a normal distribution of potassium between the cells and the extracellular fluid. The most common setting in which this does not apply is diabetic ketoacidosis, a disorder in which hyperosmolality and insulin deficiency favor the movement of potassium out of the cells. As a result, patients with this disorder may have a normal or even elevated plasma potassium concentration at presentation, despite having incurred a marked potassium deficit owing to urinary or gastrointestinal losses, or both. Potassium supplementation for these patients should begin once the plasma potassium concentration is 4.5 mEq per L or less, provided that the patient is producing urine, because the administration of insulin and fluids may cause a precipitous drop in the plasma potassium concentration.

**Potassium Preparations.** Intravenous or oral potassium chloride generally is the preferred treatment for hypokalemia. Use of the chloride salt has two important advantages. First, potassium chloride more rapidly raises the plasma potassium concentration than does potassium bicarbonate or potassium citrate, the citrate being rapidly metabolized to bicarbonate. Bicarbonate enters cells more readily than does chloride. The retention of chloride in the extracellular fluid, obligated by the need to maintain electroneutrality, limits the initial entry of potassium into the cells, thereby maximizing the rise in the plasma potassium concentration. Second, most patients with hypokalemia also have metabolic alkalosis. For example, with diuretic therapy, vomiting, and hyperaldosteronism, hydrogen loss accompanies that of potassium. Potassium must be given with chloride to such patients if both the hypokalemia and the alkalosis are to be corrected optimally (see Chapter 198). In comparison, potassium bicarbonate or potassium citrate can be given to patients with hypokalemia and metabolic acidosis, such as occurs in RTA and chronic diarrheal states.

Oral potassium chloride can be given in crystalline form (salt substitutes), as a liquid, or in a slow-release tablet or capsule. Salt substitutes contain 50 to 65 mEq per level teaspoon; they may be the ideal form of oral therapy, because they are safe, well tolerated, and much cheaper than the other preparations. Potassium chloride solutions, on the
other hand, are often unpalatable, and the slow-release preparations can, in rare cases, cause ulcerative or stenotic lesions in the gastrointestinal tract as a result of the local accumulation of high concentrations of potassium.

Merely increasing the intake of potassium-rich foods such as oranges and bananas is generally less effective in the absence of renal insufficiency. These foods contain phosphate and citrate rather than chloride and are, therefore, less likely to correct the hypokalemia and metabolic alkalosis.

Potassium chloride can be given intravenously to patients who are unable to eat or who have severe hypokalemia. It is usually added to a solution in which the concentration should generally not exceed 40 mEq of potassium per L because higher concentrations can lead to pain and sclerosis of a peripheral vein. A saline solution is preferred to a dextrose solution for initial therapy because the administration of dextrose can lead to a transient 0.2 to 1.4 mEq per L reduction in the plasma potassium concentration because of glucose-induced insulin release.

**Mild-to-Moderate Potassium Depletion.** The majority of patients have a plasma potassium concentration between 3.0 and 3.5 mEq per L; this degree of potassium depletion usually produces no symptoms, except in patients with advanced liver disease or in patients with heart disease, particularly if they are taking digoxin. Treatment in this setting is directed toward replacing the lost potassium, usually beginning with 40 to 80 mEq of potassium chloride per day, and toward treating the disorder responsible for the loss of potassium.

Potassium replacement alone may be insufficient to treat patients with ongoing urinary losses caused by chronic diuretic therapy, tubular dysfunction, or primary hyperaldosteronism. Potassium-sparing diuretics such as amiloride, triamterene, the aldosterone antagonists, spironolactone, and eplerenone are generally more effective than other agents, because they limit further urinary losses of both potassium and magnesium. It is frequently underappreciated, however, that, in the presence of high levels of aldosterone, greater-than-usual doses (up to 20 to 40 mg of amiloride and 150 to 300 mg of spironolactone) may be required to block potassium secretion. The combination of a potassium-sparing diuretic with potassium supplements should be used only with careful monitoring to prevent possible overcorrection with development of hyperkalemia and should be avoided in most patients with renal insufficiency.

**Severe Hypokalemia.** Potassium repletion is more urgent for patients with profound or symptomatic hypokalemia (i.e., arrhythmias, marked muscle weakness). This is most easily done orally. The plasma potassium concentration transiently rises by as much as 1.0 to 1.5 mEq per L after
40 to 60 mEq and by 2.5 to 3.5 mEq per L after 135 to 160 mEq. The level then falls because most of the exogenous potassium is taken up by the cells. In light of these fluxes, careful monitoring is required, and more potassium should be given as necessary. A patient with a plasma potassium concentration of 2.0 mEq per L, for example, may have a 400 to 800 mEq potassium deficit.

Some patients with severe hypokalemia must be treated intravenously because of medical instability or an inability to take medication orally. There are two potential limitations to intravenous therapy: A maximum concentration of 50 to 60 mEq per L can be administered via a peripheral vein without irritation, and, because saline solutions are preferable, volume overload is a potential risk in susceptible subjects.

The necessity for aggressive intravenous therapy occurs primarily in patients with diabetic ketoacidosis or nonketotic hyperglycemia with hypokalemia caused by marked urinary potassium losses. As described previously, treatment with insulin and fluids exacerbates the hypokalemia. Because these patients are also quite volume depleted, the addition of 40 to 60 mEq of potassium chloride to each liter of half-isotonic saline can supply large quantities of potassium with less risk of pulmonary congestion.

In general, the maximum rate of intravenous potassium administration is 10 to 20 mEq per hour, although as much as 40 to 100 mEq per hour has been given to selected patients with paralysis or life-threatening arrhythmias [38]. In these cases, solutions containing as much as 200 mEq of potassium per L (20 mEq in 100 mL of isotonic saline) have been used. They should be infused into a large vein, such as the femoral vein; a central venous line has also been used, but a local increase in the potassium concentration could have a deleterious effect on cardiac conduction.

It must be emphasized that rapid intravenous administration of potassium is potentially dangerous, even in potassium-depleted patients. Thus, careful monitoring of the physiologic effects of hypokalemia (ECG abnormalities, muscle weakness, or paralysis) is essential. Once these problems are no longer severe, the rate of potassium repletion should be slowed down to 10 to 20 mEq per hour, even though there may be persistent hypokalemia.

Hyperkalemia

Hyperkalemia is a relatively common laboratory abnormality in critically
ill patients, particularly in those with oliguric acute or chronic kidney disease.

Etiology

Hyperkalemia is rare in healthy subjects because the transcellular and renal disposal adaptations prevent significant potassium accumulation in the extracellular fluid. Furthermore, the efficiency of potassium handling is increased if potassium intake is slowly enhanced, thereby allowing what might otherwise be a fatal potassium load to be tolerated. This phenomenon, called potassium adaptation, is mostly because of more rapid potassium excretion in the urine.

Therefore, increasing potassium intake is not commonly a cause of hyperkalemia, unless the patient has an impaired capacity for potassium excretion or the potassium loading occurs too rapidly for such adaptation to occur. As examples, acute hyperkalemia can be induced (primarily in infants because of their small size) by the administration of intravenous potassium penicillin as an intravenous bolus or by the ingestion of a potassium-containing salt substitute.

The net release of potassium from the cells, either because of enhanced release or decreased entry, can also cause hyperkalemia. As with exogenous potassium loading, the elevation is typically transient because the excess potassium is excreted in the urine. Because persistent hyperkalemia requires impairment in urinary potassium excretion, it may be inferred that this problem is generally associated with a reduction in either aldosterone effect or in the delivery of sodium and water to the distal secretory site. The causes of hyperkalemia are listed in Table 199.6.

Increased Potassium Release from Cells

**Pseudohyperkalemia.** Pseudohyperkalemia refers to conditions in which the elevation in the measured plasma potassium concentration is caused by potassium movement out of the cells during or after the blood specimen has been drawn. The major cause of this problem is mechanical trauma during venipuncture, resulting in hemolysis. Because this is an in vitro phenomenon, the patient demonstrates no clinical signs and symptoms of hyperkalemia.

Potassium also moves out of white cells and platelets after clotting has occurred. Thus, the serum potassium concentration normally exceeds the true value in the plasma by as much as 0.5 mEq per L. This difference in normal levels is not clinically important. In contrast, a patient with marked leukocytosis or thrombocytosis (white cell or platelet count >100,000 per μL or 1,000,000 per μL, respectively) may have a measured serum potassium concentration as high as 9 mEq per L. This phenomenon is most often observed in patients with myeloproliferative diseases. With essential thrombocytosis, for example, the measured serum potassium concentration rises by approximately 0.15 mEq per L for every 100,000 per μL elevation in the platelet count.

Pseudohyperkalemia should be suspected whenever there is no apparent cause for an elevated plasma potassium concentration in an asymptomatic patient and particularly in patients with persistent hyperkalemia despite normal renal function. Comparing the serum potassium concentration with that in plasma (collected using a heparinized specimen tube) often establishes the diagnosis. Comparing
the serum potassium levels drawn with and without a tourniquet also may be useful diagnostically if a significant difference is observed.

**Metabolic Acidosis.** The buffering of excess hydrogen ions in the cells can lead to potassium movement into the extracellular fluid; this transcellular shift is necessitated, in part, by the need to maintain electroneutrality. This phenomenon is less likely to occur in the organic acidoses, ketoacidosis, and lactic acidosis. Although the potassium level may be elevated in both of these conditions, hyperkalemia appears to result from insulin deficiency and tissue breakdown, with potassium leakage from cells rather than from the acidosis itself.

**Insulin Deficiency, Hyperglycemia, and Hyperosmolality.** Insulin promotes potassium entry into cells; thus, the ingestion of glucose (which stimulates endogenous insulin secretion) minimizes the rise in the plasma potassium concentration induced by concurrent potassium intake. On the contrary, in patients with uncontrolled diabetes mellitus, the combination of insulin deficiency and the hyperosmolality induced by hyperglycemia frequently leads to hyperkalemia, even though a patient may be markedly potassium depleted from previously incurred urinary potassium losses.

An elevation in $P_{\text{Osm}}$ results in osmotic water movement from cells into the extracellular fluid. This is accompanied by potassium movement out of the cells. A similar rise in plasma potassium can occur with any solute that increases the effective $P_{\text{Osm}}$, such as mannitol, particularly in patients with renal failure.

Somatostatin, by inhibiting insulin release, can raise the plasma potassium concentration by an average of 0.6 mEq per L in healthy subjects but by more than 1.5 mEq per L to potentially dangerous levels in selected patients with end-stage renal disease [39].

**Increased Tissue Breakdown.** Any cause of increased tissue breakdown can result in the release of potassium into the extracellular fluid. Hyperkalemia is particularly likely to develop in this setting if renal impairment is also present. Clinical examples include breakdown of a large hematoma, as might occur in the wake of a gastrointestinal hemorrhage; rhabdomyolysis from any cause; cell breakdown in patients receiving cytotoxic or radiation therapy for lymphoma or leukemia (the tumor-lysis syndrome); and in patients with severe hypothermia.

**β-Adrenergic Blockade.** β-Adrenergic blockers interfere with the $\beta_2$-adrenergic facilitation of potassium uptake by the cells (Fig. 199.4). This effect is associated with only a minor elevation in the plasma potassium concentration in healthy subjects (<0.5 mEq per L) because the excess
potassium can be easily excreted in the urine. True hyperkalemia is rare, except in conjunction with an additional defect in potassium handling, such as a large potassium load, marked exercise, hypoaldosteronism, or renal failure.

**Exercise.** Potassium is normally released from muscle cells during exercise. The release of potassium may have a physiologic function, because the local increase in the plasma potassium concentration has a vasodilatory effect, increasing blood flow and energy delivery to the exercising muscle [40].

The increment in the systemic plasma potassium concentration is less pronounced and is related to the degree of exercise: 0.3 to 0.4 mEq per L with slow walking; 0.7 to 1.2 mEq per L with moderate exertion (including prolonged aerobic exercise such as marathon running); and as much as 2.0 mEq per L after exercise to exhaustion [41].

The rise in the plasma potassium concentration is reversed after several minutes of rest and is typically associated with mild-rebound hypokalemia (averaging 0.4 to 0.5 mEq per L below the baseline level) that may be arrhythmogenic in susceptible individuals. The degree of potassium release is attenuated by prior physical conditioning (perhaps owing to increased Na⁺/K⁺–ATPase activity) but may be exacerbated by the administration of β-blockers.

Exercise can interfere with accurate measurement of the plasma potassium concentration. Repeated fist clenching during blood drawing can acutely raise the plasma potassium concentration by more than 1 mEq per L in that forearm, thereby representing another form of pseudohyperkalemia. Careful drawing of the blood and comparison of the plasma to the serum potassium value should identify most cases [42].

**Other.** Rarer causes of hyperkalemia because of translocation of potassium from the cells into the extracellular fluid include (a) digitalis overdose from dose-dependent inhibition of membrane Na⁺/K⁺–ATPase and (b) the hyperkalemic form of periodic paralysis, an autosomal dominant disorder in which episodes of weakness or paralysis are usually precipitated by cold exposure, rest after exercise, or the ingestion of small amounts of potassium. Hyperkalemic periodic paralysis appears related to abnormalities of the skeletal muscle cell sodium channel [43].

Administration of succinylcholine to patients with burns, extensive trauma, or neuromuscular disease can also cause hyperkalemia.
Reduced Urinary Potassium Excretion

Impaired urinary potassium excretion generally requires an abnormality in one or both of the two major factors required for adequate renal potassium handling: aldosterone and distal nephron sodium and water delivery.

**Hypoaldosteronism.** Any cause of decreased aldosterone release or effect diminishes the efficiency of potassium secretion and can lead to hyperkalemia (Table 199.7). The resulting rise in the plasma potassium concentration directly stimulates potassium secretion, partially overcoming the relative absence of aldosterone. As a consequence, the rise in the plasma potassium concentration is small in patients with normal renal function, but it can be clinically important in the presence of underlying renal insufficiency or a high potassium intake.

Hyperkalemia in hypoaldosteronism is usually associated with a mild metabolic acidosis. This condition has been called type-4 RTA and appears to be primarily caused by decreased urinary ammonium excretion.

Although aldosterone also promotes sodium retention, decreased
availability of aldosterone is not typically associated with prominent sodium wasting with type-4 RTA in adults because of the ability of other antinatriuretic factors such as angiotensin II and norepinephrine to compensate. Hyponatremia is also uncommon because there is no hypovolemic stimulation for ADH release. If hyponatremia is present, primary adrenal insufficiency should be suspected. In this disorder, the concurrent lack of cortisol is a potent stimulus to ADH secretion, leading to water retention and a fall in the plasma sodium concentration.

The causes of hypoaldosteronism include disorders that affect adrenal aldosterone synthesis, the renal response to aldosterone, or renal (and perhaps adrenal) renin release (Table 199.7).

**Hyporeninemic Hypoaldosteronism.** The syndrome of hyporeninemic hypoaldosteronism, a form of type-4 RTA, is characterized by coexisting defects in the release of renin by the kidney and aldosterone by the adrenal cortex. This relatively common disorder most often occurs in patients with mild-to-moderate renal insufficiency as a result of diabetic nephropathy or chronic interstitial nephritis. Low plasma renin levels are common in diabetic patients, partly because of a defect in the conversion of the precursor prorenin into active renin. Volume expansion induced by diabetes and other chronic kidney diseases may play a contributory role; the increase in atrial natriuretic peptide release in this setting can suppress both the release of renin and the hyperkalemia-induced secretion of aldosterone. Similar hemodynamic and humoral changes occur in the acute nephritic syndrome of postinfectious glomerulonephritis. For some patients, these changes can lead to hyperkalemia that responds to mineralocorticoid replacement. Recovery of renal function within 1 to 2 weeks is associated with restoration of normal potassium balance.

Low renin and aldosterone levels may also occur in several other settings:

*NSAIDs.* NSAIDs lower renal renin secretion, which is normally partially mediated by locally produced prostaglandins. The result is that the plasma potassium concentration rises approximately 0.2 mEq per L in subjects with normal renal function but can rise by more than 1.0 mEq per L in the setting of renal insufficiency. This can occur with specific cyclooxygenase-2 inhibitors as well as nonselective NSAIDs.

*ACE inhibitors, ARBs, and direct renin inhibitors.* Similar considerations apply to agents that block the production or action of angiotensin II, because angiotensin II is necessary for normal aldosterone release in response to volume depletion or hyperkalemia.

*Other.* Other causes of hyporeninemic hypoaldosteronism include the
use of cyclosporine and tacrolimus, which can lead to hyperkalemia in renal transplant recipients, likely from diminished secretion of and responsiveness to aldosterone [44]. The administrations of the antibiotics trimethoprim and pentamidine are other causes of hyperkalemia. Both agents appear to close sodium channels in the distal nephron in a manner similar to that of the potassium-sparing diuretic amiloride.

Primary Adrenal Insufficiency. Primary adrenal cortical failure (also called Addison’s disease) is associated with lack of cortisol and aldosterone. Pituitary disease, in comparison, does not lead to hypoaldosteronism because ACTH does not have a major role in the regulation of aldosterone release. Primary adrenal insufficiency is frequently because of autoimmune destruction of the steroid-producing cells in the adrenal cortex.

Potassium-Sparing Diuretics. Potassium-sparing diuretics are probably the most common cause of hyperkalemia because of impairment of aldosterone function. These drugs antagonize the action of aldosterone on the collecting tubule cells. Spironolactone and eplerenone compete for the aldosterone receptor, whereas amiloride and triamterene close the sodium channels in the luminal membrane.

Heparin. Commercial heparin preparations exert a direct toxic effect on the zona glomerulosa cells of the adrenal cortex [45]. Even low-dose heparin can lead to a 75% reduction in plasma aldosterone levels. The mechanism appears to involve a reduction in the number and affinity of adrenal angiotensin II receptors involved in aldosterone synthesis and release.

Adrenal Enzyme Deficiency. In children, hypoaldosteronism can result from a deficiency of enzymes required for aldosterone synthesis, which may be associated with concurrent abnormalities in cortisol and androgen production.

Pseudohypoaldosteronism. Decreased aldosterone activity also occurs in the syndrome of pseudohypoaldosteronism. This disorder is associated with generalized resistance to the actions of aldosterone owing to a marked reduction in the number of mineralocorticoid receptors in the kidney and in other target organs such as the colon and sweat glands.

Severe Illness. Hypoaldosteronism caused by decreased adrenal
production is common in critically ill patients. The stress-induced hypersecretion of ACTH in these patients may be responsible for this defect by inducing activity of 17α-hydroxylase in the zona glomerulosa. This enzyme enhances the synthesis of cortisol at the expense of aldosterone.

**Chronic Kidney Disease.** The ability to maintain potassium excretion at near-normal levels is generally maintained in patients with renal disease as long as both aldosterone secretion and distal tubular urine flow are maintained. Patients who are oliguric or who have an additional problem such as a high potassium intake, increased tissue breakdown, or hypoaldosteronism are predisposed to hyperkalemia.

**Effective Circulating Volume Depletion.** Decreased distal tubular urine flow owing to marked effective volume depletion, as might occur in heart failure or hepatic cirrhosis, can lead to hyperkalemia. In this setting, there is also a fall in the quantity of sodium presented to the potassium secretory site in the collecting tubule. Hyperkalemia may occur even though aldosterone activity is high.

**Hyperkalemic Type-1 Renal Tubular Acidosis.** In some patients with type-1 (distal) RTA, the primary defect is impaired sodium reabsorption in the cortical collecting tubule. The movement of sodium from the lumen into the cell at this site makes the lumen electronegative, thereby promoting both hydrogen and potassium secretion. Inhibiting the transport of sodium, therefore, reduces both hydrogen and potassium secretion, leading to metabolic acidosis and hyperkalemia. This form of type-1 RTA is most often seen in patients with urinary tract obstruction or sickle cell disease. Patients with type-1 RTA have normal or even high aldosterone levels and are unable to acidify the urine normally (urine pH ≤5.0), in contrast to individuals with hypoaldosteronism and other forms of type-4 RTA who frequently exhibit a urine pH of less than 5.3.

**Clinical Manifestations**

The symptoms induced by hyperkalemia are related to impaired neuromuscular transmission. The ease of generating an action potential, called *membrane excitability*, is related both to the magnitude of the resting membrane potential and to the activation state of membrane sodium channels. Opening of these sodium channels, leading to the passive diffusion of extracellular sodium into the cells, is the primary step in this process. According to the Nernst equation, the resting membrane potential is related to the ratio of the intracellular and the extracellular potassium concentration. An elevation in the extracellular potassium concentration decreases this ratio and, therefore, partially depolarizes the
cell membrane, thereby making the resting potential less electronegative. This change initially increases membrane excitability because less of a depolarizing stimulus is required to generate an action potential. However, persistent depolarization inactivates sodium channels in the cell membrane, thereby producing a net decrease in membrane excitability that may be manifested clinically by impaired cardiac conduction or muscle weakness, or both, or by paralysis. 

In general, severe symptoms of hyperkalemia do not occur until the plasma potassium concentration is more than 7.5 mEq per L. There is, however, substantial interpatient variability because factors such as hypocalcemia and metabolic acidosis can increase the toxicity of excess potassium. Thus, careful monitoring of the ECG and muscle strength is indicated to assess the functional consequences of the hyperkalemia. A plasma potassium concentration of more than 7.5 to 8.0 mEq per L, severe muscle weakness, or marked ECG changes are potentially life threatening and require immediate treatment using the modalities described here [46].

The earliest ECG abnormality is symmetric peaking of T waves, followed by reduced P-wave voltage and widening of QRS complexes (Fig. 199.7). If untreated, severe hyperkalemia can cause the normal QRS morphology to be lost altogether so that the ECG pattern deteriorates into a sinusoidal ECG form, with one oscillation representing a wide QRS complex and the complementary oscillation representing an abnormal T wave. ECG changes usually do not appear until the plasma K+ concentration exceeds 6.5 mEq per L, and are more likely to develop when the rise in K+ occurs rapidly.

![Figure 199.7](image)

**FIGURE 199.7** Marked hyperkalemia results in peaked T waves and widened QRS complexes in this electrocardiogram.

The neuromuscular manifestations of hyperkalemia are nonspecific. The earliest findings are paresthesias and weakness, which can progress
to paralysis affecting the respiratory muscles. These symptoms are similar to those seen with hypokalemia; cranial nerve function remains unaffected.

**Treatment**

An asymptomatic patient with a plasma potassium concentration of 6.5 mEq per L and no ECG changes can be treated with a cation exchange resin (Kayexalate) alone, and patients with a level below 6.0 mEq per L can often be treated just with a low-potassium diet and diuretics. Any extra source of potassium intake (salt substitutes, potassium supplements, and foods with a high potassium content) should be eliminated, and any potentiating drugs (e.g., NSAIDs or ACE inhibitors) should be discontinued.

Specific treatment of severe or symptomatic hyperkalemia is directed at antagonizing the membrane effects of potassium, driving extracellular potassium into the cells, or removing excess potassium from the body. The following modalities, which are listed according to their rapidity of action, all may be beneficial.

**Calcium.** Calcium directly antagonizes the membrane actions of hyperkalemia. As mentioned previously, hyperkalemia-induced depolarization of the resting membrane potential leads to inactivation of sodium channels and decreased membrane excitability. Calcium antagonizes this membrane effect of hyperkalemia, although how this is achieved is not well understood.

The protective effect of calcium begins within minutes but is relatively short lived. As a result, calcium infusions are indicated only for severe hyperkalemia, when it is potentially dangerous to wait the 30 to 60 minutes required for insulin and glucose or sodium bicarbonate to act. The usual dose is 10 mL (1 ampule) of a 10% calcium gluconate solution infused slowly during 2 to 3 minutes with constant cardiac monitoring. This dose can be repeated after 5 minutes if the ECG changes persist.

Calcium should not be given in bicarbonate-containing solutions because this can lead to its precipitation as calcium carbonate. Because hypercalcemia can induce digitalis toxicity, calcium should be administered only when absolutely necessary to patients taking digoxin.

**Insulin and Glucose.** Increasing the availability of insulin lowers the plasma potassium concentration by driving potassium into the cells by enhancing the activity of the Na\(^+\)/K\(^+\)–ATPase pump in skeletal muscle. Hyperinsulinemia can be induced either by giving insulin with glucose to prevent hypoglycemia or by the intravenous administration of glucose (50 mL of a 50% glucose solution), which rapidly enhances endogenous
insulin secretion in a nondiabetic patient. Glucose alone may produce a smaller rise in the plasma insulin concentration and a lesser reduction in plasma potassium concentration than does the insulin plus glucose regimen. Effective therapy usually produces a 0.5 to 1.5 mEq per L fall in the plasma potassium concentration. This effect begins in 15 minutes, peaks at 60 minutes, and lasts for several hours.

Exogenous insulin can induce symptomatic hypoglycemia unless adequate glucose is given concurrently. If, for example, 10 units of regular insulin are given with 25 g of glucose, the plasma glucose concentration may fall to less than 55 mg per dL in as many as 75% of initially normoglycemic patients. Increasing the initial glucose dose to 40 g, followed by a continuous dextrose infusion, generally prevents this problem.

Proper therapy in diabetic patients varies with the plasma glucose concentration. Both insulin and glucose should be given when the plasma glucose concentration is normal or mildly elevated because endogenous insulin release is impaired. Insulin in this case reduces the plasma potassium concentration directly by preventing a rise in the plasma glucose concentration that can exacerbate the hyperkalemia. The osmotic force generated by the high extracellular glucose concentration pulls water and, secondarily, potassium out of the cells. In comparison, insulin alone is sufficient if the patient is already hyperglycemic.

**Sodium Bicarbonate.** Raising the systemic pH with sodium bicarbonate promotes hydrogen ion release from the cells and a reciprocal movement of potassium into the cells. The elevation in the plasma bicarbonate concentration appears to have another direct, albeit not delineated, effect on lowering the plasma potassium concentration that is independent of pH.

The potassium-lowering action of sodium bicarbonate is most prominent for patients with metabolic acidosis, beginning within 30 to 60 minutes and persisting for several hours. Sodium bicarbonate appears to be less effective in correcting hyperkalemia for patients with renal failure. Insulin plus glucose or a $\beta_2$-agonist is more predictably effective in this setting.

The usual dose is 45 mEq (1 ampule of a 7.5% sodium bicarbonate solution) infused slowly during 5 minutes; this dose can be repeated in 30 minutes if necessary. Alternatively, sodium bicarbonate can be added to a glucose and saline solution. This regimen may have an additional advantage in hyponatremic patients because raising the plasma sodium concentration with this hypertonic solution can also reverse the ECG effects of hyperkalemia. Both an increase in the rate of membrane depolarization and a fall in the plasma potassium concentration by dilution may contribute to this effect. These sodium-containing solutions
should be used with extreme caution in edematous patients with advanced heart failure or renal failure. Despite the physiologic rationale, bicarbonate administration appears to be less effective in lowering the serum potassium concentration in patients with end-stage renal disease who are receiving dialysis.

**β₂-Adrenergic Agonists.** Like insulin, β₂-adrenergic agonists drive potassium into the cells by increasing Na⁺/K⁺–ATPase activity. Albuterol (20.0 mg in 4 mL of saline by nasal inhalation for 10 minutes or 0.5 mg by intravenous infusion) can lower the plasma potassium concentration by 0.5 to 1.5 mEq per L within 30 to 60 minutes. Furthermore, the effect of these agents is additive to that of insulin plus glucose. The only common side effects of the β₂-agonists are mild tachycardia and the possible induction of angina in susceptible individuals. Thus, these agents should probably be avoided in patients with known active coronary disease.

**Loop or Thiazide Diuretics.** Loop and thiazide diuretics can be used when hyperkalemia is present in an individual with hypertension or volume overload. However, the effectiveness of diuretic therapy is frequently limited by moderate-to-severe renal insufficiency.

**Cation Exchange Resin.** The most readily available cation exchange resin is sodium polystyrene sulfonate (SPS). In the gut, this resin takes up potassium, and calcium and magnesium to lesser degrees, and releases sodium. Each gram of resin may bind as much as 1 mEq of potassium and release 1 to 2 mEq of sodium. Thus, a potential side effect is exacerbation of any preexisting degree of sodium overload.

The resin can be given either orally or as a retention enema. The oral dose is usually 15 to 30 g. This can be repeated every 4 to 6 hours as necessary. Lower doses (5 to 10 g with meals) are generally well tolerated (no nausea or constipation) and can be used to control chronic mild hyperkalemia in patients with renal insufficiency. Historically, SPS was given with sorbitol to prevent constipation. Intestinal necrosis is a rare complication and has been associated with the use of concomitant sorbitol [47]. After issuance of an FDA black-box warning on the combination of sorbitol and SPS, preparations of SPS containing 70% sorbitol were removed from the market, and the combination is generally not recommended [47].

Recently, there have been reports questioning the effectiveness of SPS.
This issue remains unresolved at this time, but anecdotal experience supports its effectiveness in lowering the serum potassium levels for many patients. Still, with the possible, although uncommon, risk of bowel injury, other measures should be tried first.

Two novel agents have recently been studied for the treatment of hyperkalemia in placebo controlled trials. Patiromer is a powder comprised of spherical beads that binds potassium in the colon in exchange for calcium. Sodium zirconium cyclosilicate has a lattice structure and acts as a cation exchanger which entraps potassium in exchange for hydrogen and sodium. Neither of these compounds are approved by the FDA [48].

Dialysis. Dialysis can be used if the conservative measures listed in the preceding sections are ineffective, if the hyperkalemia is severe, if the patient has marked tissue breakdown and is releasing large amounts of potassium from the injured cells, or, of course, if the patient has hyperkalemia in the setting of renal failure. The rate of potassium removal with hemodialysis is preferred in the last two settings because it is many times faster than with peritoneal dialysis.

OVERVIEW OF ACUTE KIDNEY INJURY

Sudden disruption of previously normal or stable kidney function, usually occurring over hours or days, is termed acute kidney injury (AKI), formerly referred to as acute renal failure. AKI occurs in diverse clinical contexts with varied presentations and etiologies. The course of AKI differs from that of chronic kidney disease (CKD), in which renal function declines more slowly.

AKI is often diagnosed when a patient develops an elevation in the blood urea nitrogen (BUN) and serum creatinine. This change typically results from a decline in glomerular filtration rate (GFR), but in certain cases may reflect increased urea and/or creatinine production without any reduction in GFR (Table 200.1). Oliguria, a reduction in urine output to less than 20 mL per hour, may be present, although many forms of AKI are nonoliguric. When tubular reabsorption of glomerular filtrate is reduced as a result of either tubular dysfunction or diuretic administration, patients may be polyuric even though GFR is markedly reduced.

**TABLE 200.1 Causes of Blood Urea Nitrogen or Serum Creatinine Elevation Without Reduction of Glomerular Filtration Rate**

- Increased biosynthesis of urea
- Gastrointestinal bleeding
Even a small rise in serum creatinine correlates with increased mortality [1,2]. However, AKI can occur prior to a significant increase in creatinine. This is especially true in the ICU setting, where frequent administration of large volume of intravenous fluids can dilute serum creatinine. Therefore, the Acute Dialysis Quality Initiative Group has proposed a classification of AKI based not only on serum creatinine, but also on the degree of urinary output reduction and the requirement for renal replacement therapy [3]. This classification is reflected in the RIFLE criteria (Table 200.2), which have been shown to predict renal outcome and mortality in a variety of critically ill and hospitalized patients [4,5]. Acute Kidney Injury Network and, recently, Kidney Disease Improving Global Outcomes initiative (KDIGO) developed a simplified, three-stage system, which is similarly based on changes in serum creatinine and urinary output (Table 200.3).

AKI may stem from any of three general conditions: impaired renal perfusion without parenchymal injury, damage to the renal parenchyma, or obstruction of the urinary tract. These etiologies are referred to as prerenal, renal, or postrenal causes of AKI, respectively, and are summarized in Table 200.4. Although it is helpful to consider the complete array of renal diseases when evaluating AKI, in the inpatient setting two-thirds of cases will be due to either acute tubular necrosis (ATN) or prerenal azotemia. Hence, an extensive search for other forms of renal disease is indicated in the intensive care unit (ICU) setting only when suggested by clinical signs or laboratory findings such as urinary abnormalities indicative of glomerular disease.

Prerenal Azotemia and Autoregulatory Failure

Prerenal azotemia develops when renal perfusion pressure decreases to a point at which GFR falls. This is a functional condition without associated renal parenchymal injury, although it may be superimposed on pre-existing CKD. The causes of prerenal azotemia are listed in Table 200.5. Normalization of renal blood flow, if possible, promptly restores renal function.

Autoregulatory failure
Nonsteroidal anti-inflammatory drugs
(preglomerular vasoconstriction)
Angiotensin-converting enzyme inhibitors
(postglomerular vasodilation)

Hypovolemia from gastrointestinal losses, hemorrhage, venous pooling, sequestering of fluid in “third spaces,” or excessive urinary or skin losses of sodium and water may cause prerenal azotemia. Patients will usually exhibit signs of volume depletion, including thirst, diminished skin turgor and dry mucous membranes, and postural hypotension. Patients whose vascular volume is functionally reduced by the hemodynamic alterations of congestive heart failure, cirrhosis, or hypoalbuminemia may develop prerenal azotemia despite having a normal or even expanded extracellular fluid (ECF) volume. Because the effective circulatory volume is reduced, renal perfusion is impaired just as in true hypovolemia.

When glomerular perfusion is threatened, autoregulatory mechanisms help maintain glomerular capillary pressure. If autoregulatory mechanisms are inoperative, a given reduction in renal blood flow
provokes a sharper decline in GFR. The mechanisms of these processes are shown in Figure 200.1. Use of nonsteroidal anti-inflammatory drugs (NSAIDs) in patients with renal hypoperfusion, for example, can lead to severe AKI. Likewise, administration of angiotensin-converting enzyme (ACE) inhibitors in patients whose renal blood flow is obstructed by bilateral renovascular renal artery stenosis can cause severe azotemia.

**FIGURE 200.1** Diagrammatic representation of autoregulation and deregulation caused by use of either nonsteroidal anti-inflammatory drugs (NSAIDs), which lead to afferent (Aff.) vasoconstriction, or angiotensin-converting enzyme (ACE) inhibitors, which produce efferent (Eff.) vasodilation. Angiotensin II, angiotensin II; GFR, glomerular filtration rate; PGs, prostaglandins.

Reduced renal perfusion slows down the flow of filtrate through the renal tubules, enhancing the reabsorption of urea. Because creatinine is not reabsorbed in the renal tubules, its clearance is unaffected by these nephronal factors. Thus, the clearance of urea is reduced disproportionately to that of creatinine, explaining the unusually high BUN–creatinine ratio that is often seen in prerenal states. In such situations, the BUN–creatinine ratio typically exceeds 20 to 1.

A high urea–creatinine ratio, however, is not pathognomonic of prerenal azotemia. When urea production is accelerated in catabolic states (as is seen with tetracycline or corticosteroid therapy) or by resorption of a large hematoma or with gastrointestinal bleeding, BUN levels rise unless renal urea clearance can increase to meet the augmented urea burden. To establish whether a high BUN–creatinine ratio is due to increased urea production or reduced excretion,
calculation of the fractional urea clearance may be useful.

The hallmark of prerenal conditions is the intense renal conservation of salt and water as reflected in the urine composition, which generally shows a low sodium concentration \( U_{Na} < 10 \text{ mEq per L} \); fractional excretion of sodium \( \text{FE}_{Na} < 1\% \) and a high osmolality \( U_{Osm} > 500 \text{ mOsm per kg} \). Renal conservation of sodium involves both proximal and distal tubular mechanisms. A low urinary sodium concentration is expected in these states, whereas high urinary sodium in prerenal cases signifies a coexisting abnormality of tubular function, the effect of diuretics, or the presence of nonreabsorbable anionic substances in the urine, such as bicarbonate in patients with metabolic alkalosis, or certain penicillins, that obligate the excretion of cations like sodium. Impaired sodium reabsorption is also seen during osmotic diuresis and in certain forms of chronic renal disease.

**Intrinsic Renal Disease**

Reduced renal function may also result from renal parenchymal injury. Such injury may arise from glomerular, vascular, and tubulointerstitial disorders (Table 200.4) and may represent either primary kidney disease or the renal effects of an underlying systemic illness (e.g., systemic lupus erythematosus).

**Glomerular and Vascular Diseases**

The GFR may be abruptly reduced in acute glomerulonephritis. Patients may present with the constellation of hypertension, edema, azotemia, and hematuria, known as the *acute nephritic syndrome*. Hypertension and edema result from impaired excretion of salt and water. Although the history of a previous sore throat or streptococcal infection may provide diagnostic clues, the urinalysis is particularly valuable. The urine may be grossly bloody or tea colored. The urinary sediment contains red blood cells (RBCs) and often RBC casts (Fig. 200.2).
Typical urinary sediments from patients with parenchymal renal diseases. A: Sediment from patient with acute glomerulonephritis showing free red blood cells and red blood cell casts. B:
Sediment from patient with acute interstitial nephritis demonstrating pyuria and white blood cell cast. C: Typical muddy brown, coarse, granular casts in a patient with acute tubular necrosis.

Poststreptococcal glomerulonephritis, the prototypic nephritic disorder, often presents with AKI and oliguria. The crescentic glomerulonephritides (rapidly progressive glomerulonephritis [RPGN]), such as antiglomerular basement membrane disease and ANCA-associated glomerulonephritis, can also cause AKI. Similar findings are frequent in patients with other primary nephritic disorders as well as in secondary nephritides, such as systemic lupus erythematosus and bacterial endocarditis.

Diseases affecting either the main renal arteries or their branches may precipitate AKI. Renal artery occlusion by acute thrombosis or thromboembolism typically only causes AKI, if it is bilateral or involves a solitary functioning kidney. These processes may be silent or may produce flank pain and hematuria, particularly if abrupt enough to cause renal infarction. Fever, moderate leukocytosis, and an elevated serum level of lactate dehydrogenase should raise the suspicion of infarction. With rare exceptions, renal arterial thromboembolism occurs only in the settings of acute myocardial infarction, atrial fibrillation, bacterial endocarditis, cardiac valvular disease, or hypercoagulable disorders.

Acute renal vein thrombosis (RVT) seldom causes renal failure unless both kidneys are simultaneously occluded. Acute flank pain and hematuria are the clinical hallmarks. Renal venous obstruction may occur as a complication of nephrotic syndrome and renal cell carcinoma.

Microscopic occlusion of smaller vessels occurs in a variety of disorders, including atheroembolic renal disease, thrombotic thrombocytopenic purpura (TTP) and hemolytic–uremic syndrome, scleroderma, postpartum kidney injury, and malignant hypertension. Scleroderma or malignant hypertension may appear as AKI, with severe blood pressure elevation due to activation of the renin–angiotensin system. These vascular disorders produce renal injury by reducing glomerular blood flow. Because the lesion is proximal to the glomerulus, the urine sediment is usually acellular and bland.

Vasculitis produces AKI either through direct involvement of the renal arterial system or by inducing glomerulonephritis. Often, microscopic polyarteritis or granulomatosis with polyangiitis (formerly Wegener granulomatosis) may present with evident renal parenchymal disease, as suggested by urinary abnormalities such as microscopic hematuria, RBC
casts, and proteinuria. Patients may require ICU care when there is multiorgan involvement, such as the pulmonary disease that occurs in granulomatosis with polyangiitis. Fulminant presentations with severe hypoxemia and pulmonary hemorrhage may be accompanied by rapidly progressive renal dysfunction. In these cases, glomerular involvement may range from focal and segmental necrotizing glomerulitis to severe crescentic glomerulonephritis.

Tubulointerstitial Diseases

Two syndromes are responsible for most cases of parenchymal AKI in hospitalized populations: ATN and acute interstitial nephritis (AIN).

Acute Tubular Necrosis. ATN is a syndrome that may result from renal ischemia or exposure to nephrotoxins such as aminoglycoside antibiotics, radiocontrast agents, heavy metals, and myoglobin. Despite the term acute tubular necrosis, frank tubular cell necrosis does not appear in all cases. Historically, the pathophysiology of AKI in ATN has been attributed to three processes: (a) obstruction of tubular lumens by sloughed epithelial cells and cellular debris, (b) back-leak of filtered wastes into the circulation through the disrupted tubular epithelium, and (c) sustained reduction in glomerular blood flow following the inciting stimulus. For instance, severe cortical vasoconstriction has been noted early in the course of ATN, which is likely mediated by endothelial cell injury and locally acting vasoconstrictors, such as endothelin. Afferent arteriolar vasoconstriction has also been described. In ATN, impaired proximal solute reabsorption increases distal chloride delivery to macular densa, which, in turn, mediates afferent constriction via the secretion of adenosine. This process is termed tubuloglomerular feedback. However, it remains unclear whether renal vasoconstriction has a central role in the pathogenesis of ATN, because restoring renal blood flow with vasodilators does not always preserve the GFR. Nonetheless, this process may be important in the initiation of certain forms of ATN such as radiocontrast toxicity.

As already noted, relatively modest hypoperfusion leads to prerenal azotemia, characterized by a modest reduction in urine output and GFR, and preservation of tubular function, which is rapidly reversible. However, a more critical decrease in renal perfusion leads to medullary hypoperfusion and ischemic ATN with greater reductions in GFR, abnormalities of tubular function, and often histologic evidence of tissue injury. Because recovery depends on cellular regeneration, reversal of ATN is much slower than for prerenal azotemia. The most extreme form of hypoperfusion injury is cortical ischemia associated with either patchy or diffuse cortical necrosis, typically manifesting the most severe
reduction in GFR and a much less certain prognosis for recovery of renal function. The medullary thick ascending limb segment of the loop of Henle is particularly vulnerable to ischemic and nephrotoxic insults because of a combination of low ambient partial pressure of oxygen and intense, transport-driven oxygen consumption. Other factors, such as adenosine triphosphate depletion activation of phospholipases, cytosolic and mitochondrial calcium overload, and release of free radicals, may contribute to cellular damage.

The immune system plays a critical role in pathogenesis of ATN through recruitment of various inflammatory cells, cytokine release, complement activation, and induction of tubular cell apoptosis [6,7]. Adhesion molecules, such as intracellular adhesion molecule 1 (ICAM-1), appear to play a role in the development of postischemic ATN in experimental animal models. However, anti-ICAM antibody failed to protect against ischemic AKI in a clinical trial of kidney transplant patients [8]. Another regulatory molecule expressed in the kidney, the protein neutrophil gelatinase-associated lipocalin (NGAL), is released early in the course of ischemic ATN and appears to attenuate tubular cell injury and apoptosis [9]. There is considerable interest in using NGAL and other molecules as biomarkers of early kidney injury (Table 200.6) with the hope that timely diagnosis of AKI will allow clinicians to make therapeutic interventions that will ultimately improve outcomes (discussed further in “Diagnosis” section).

| **TABLE 200.6 Protein Biomarkers for the Early Detection of Acute Kidney Injury** |
|-----------------------------|---------------------------------|
| **Biomarker**              | **Associated injury**           |
| Cystatin C                  | Proximal tubule injury          |
| KIM-1                       | Ischemia and nephrotoxins       |
| NGAL                        |                                 |
| L-FABP                      |                                 |
| Netrin-1                    | Sepsis, ischemia, nephrotoxins I|
| NHE3                        | Prerenal, ischemia, and postrenal|
| α-GST                       | Acute rejection, proximal tubule injury|
| π-GST                       | Acute rejection, distal tubule injury|
| Cytokines (IL-6, IL-8, IL-18)| Delayed graft function         |
| Actin–actin                 | Tubular cell cycle arrest in    |
depolymerizing F Keratin-derived chemokine
IGFBP7
TIMP-2

GST, glutathione S-transferase; IL, interleukin; KIM, kidney injury molecule; L-FABP, L-type fatty acid–binding protein; NGAL, neutrophil gelatinase-associated lipocalin; NHE, sodium–hydrogen exchanger; IGFBP7, insulin-like growth factor–binding protein 7; TIMP-2, tissue inhibitor of metalloproteinases-2.

History of exposure to a predisposing factor, such as prolonged ischemia or toxin, can be elicited in approximately 80% of patients with ATN. Most individuals with this syndrome have the classic findings of sloughed renal tubular epithelial cells, epithelial cell casts, or muddy brown granular casts in the urinary sediment (Fig. 200.2). These findings are not seen in prerenal azotemia. In addition, calculating the fractional excretion of filtered sodium (\( \text{FE}_{\text{Na}} \)) may enable the clinician to differentiate between ATN and prerenal azotemia. The \( \text{FE}_{\text{Na}} \) expresses urinary sodium excretion as a percentage of filtered load. It provides a more precise representation of tubular sodium avidity than the urinary sodium concentration, because it is not influenced by changes in urine concentration or flow rate. The \( \text{FE}_{\text{Na}} \) is very low in prerenal azotemia as a result of active sodium reabsorption by the renal tubules. When frank tubular damage has occurred, as in ATN, the tubules can no longer reclaim sodium efficiently, and the \( \text{FE}_{\text{Na}} \) is generally high (Fig. 200.3). See “Diagnosis” section for more detail on the \( \text{FE}_{\text{Na}} \). Urinary concentration is also impaired in tubular necrosis; as a result, urinary osmolality approximates that of plasma, and the ratio of BUN to creatinine is less than 20.
FIGURE 200.3 Diagnostic parameters in acute renal failure. Two laboratory tests used to distinguish prerenal (PR) azotemia from acute tubular necrosis (ATN) are shown. Left: Urinary sodium concentration ($U_{Na}$, mEq per L). Right: Fractional excretion of sodium (FE$_{Na}$, %). Area within each symbol denotes the proportion of patients with each condition correlated with the laboratory parameter. Note that although considerable numbers of patients with PR and ATN fall in an intermediate zone of $U_{Na}$ (20 to 40 mEq per L), the FE$_{Na}$ almost completely differentiates the two groups.

**Acute Interstitial Nephritis.** The term *acute interstitial* (or *tubulointerstitial*) *nephritis* encompasses a collection of disorders characterized by acute inflammation of the renal interstitium and tubules. Depending on the specific nature of the condition, the inflammatory infiltrate may consist of a combination of neutrophils, eosinophils, and lymphocytes or plasma cells. Most cases of AIN represent an allergic reaction with eosinophilia and skin eruptions, usually induced by medication. Interstitial disease can also occur as a result of infectious agents, including brucellosis, leptospirosis, legionella,
toxoplasmosis, and Epstein–Barr virus.

These disorders are to be distinguished from the familiar entity acute pyelonephritis. Acute pyelonephritis is a suppurative disease of the tubulointerstitium, usually caused by bacterial infection ascending from the urinary bladder. Acute pyelonephritis rarely causes renal dysfunction. AIN, however, is an important cause of AKI and is discussed in detail later.

**Postrenal Azotemia**

The term *postrenal azotemia*, or *obstructive uropathy*, refers to azotemia caused by obstruction of urine flow from the kidneys. Renal outflow obstruction has many causes, but the most common causes are prostatic enlargement, nephrolithiasis, and genitourinary tumors. For obstruction to produce azotemia, both kidneys must be involved because one normally functioning kidney is sufficient to maintain a near-normal GFR. AKI may occur with unilateral obstruction in a patient who has one functioning kidney or in whom unilateral obstruction is superimposed on underlying CKD.

The clinical history often helps with the diagnosis of obstructive uropathy. Prior kidney stones should raise the index of suspicion for obstruction, particularly in the setting of symptoms of renal colic. AKI in an elderly man who has been experiencing urinary hesitancy most likely represents obstruction of the bladder outlet by an enlarged prostate. A history of genitourinary malignancy in an azotemic patient also makes obstruction the most likely diagnosis. AKI in the setting of painless gross hematuria and a history of NSAID use should prompt a suspicion of papillary necrosis, a condition in which sloughed-off renal papilla can cause bilateral ureteral obstruction. Finally, renal failure in a newborn infant is likely to be due to congenital anatomic ureteral obstruction.

When urine output declines precipitously or ceases entirely (anuria), complete obstruction of the urinary tract must be ruled out. Such an obstruction is likely to be located at the bladder outlet because the probability of simultaneous obstruction in both ureters from any cause is remote. If the patient has only one kidney (e.g., due to previous nephrectomy, unilateral renal disease, or congenital solitary kidney), however, anuria may occur with unilateral ureteral obstruction. Even though complete obstruction is a common cause of anuria, partial obstruction is not always associated with a decline in urine output. With partial obstruction, damage to the kidney may impair the ability to concentrate urine, resulting in a polyuric state (acquired nephrogenic diabetes insipidus). In patients with complete unilateral obstruction of a ureter, the contralateral kidney often sustains a normal urine output.

Obstructive uropathy is associated with other defects of the distal
nephron, including hydrogen ion and potassium secretion, as well as urinary concentration. Consequently, the patient, particularly if there is prolonged high-grade obstruction, may present with hyperkalemia, hyperchloremic metabolic acidosis, hypernatremia, or a combination of all three.

As discussed later, urologic causes of AKI are best diagnosed by renal imaging techniques. The urine chemistry is generally of little help in diagnosing obstructive uropathy. Likewise, the urinalysis provides only indirect evidence of a possible cause of AKI. Hematuria reflects trauma to the urinary epithelium caused by the obstructing lesion. Crystals (calcium oxalate or uric acid) in the urine sediment may suggest a kidney stone.
CLINICAL SYNDROMES ASSOCIATED WITH AKI IN THE INTENSIVE CARE SETTING

With the higher level of acuity of illness, and more radical approaches to surgical and pharmacologic therapeutics, the incidence of AKI is increasing. As with other areas of clinical medicine, patterns of presentation often can be recognized and can lead the physician to the most likely diagnoses. The following section explores in greater detail the specific AKI syndromes most commonly encountered in the ICU (listed in Table 200.7).

TABLE 200.7 Intensive Care Syndromes Associated with Acute Kidney Injury (AKI)

Ischemic AKI
- Extracellular volume depletion
- Postoperative (particularly cardiac surgery)
- Severe ventricular dysfunction or cardiogenic shock
- Sepsis
- Pancreatitis
- Trauma
- Burns
- Acute bilateral cortical necrosis

Nephrotoxicity and drug-induced AKI
- Myoglobinuric AKI
- Radiocontrast nephropathy
- Drugs (see Table 200.13)

Renal vascular disease
- Major vessel disease
  - Renal artery embolism or thrombosis
  - Renal vein thrombosis
- Microvascular disease
  - Atheroembolism
  - Vasculitis
  - Scleroderma

Cancer related
Obstructive uropathy
Hypercalcemia
Tumor-lysis syndrome
ATN secondary to chemotherapy
Renal dysfunction with liver disease
Prerenal azotemia
ATN
Hepatorenal syndrome

ATN, acute tubular necrosis.

Ischemic Acute Kidney Injury

The most common forms of AKI in the ICU result from renal hypoperfusion. Because frank hypotension is documented in fewer than half of these cases, the causal events may often be overlooked or obscured by multiple factors. Frequently, more than one causal factor is necessary to provoke AKI. For example, the presence of hypovolemia enhances the risk for AKI due to nephrotoxic insults.

Extracellular Volume Depletion

Extracellular volume depletion accounted for approximately 15% to 20% of cases of AKI. In most instances, urinary losses are the cause of hypovolemia. Injudicious use of diuretics and the osmotic diuresis that accompanies diabetic hyperglycemia are the most common etiologies. Cessation of diuretic therapy and volume repletion lead to rapid recovery; consequently, the mortality is quite low.

In rare instances, gastrointestinal losses of substantial magnitude may lead to AKI. (In the developing world, however, this is one of the most common causes of AKI and the major cause of morbidity and mortality where cholera is endemic.) In such cases, the source of the gastrointestinal losses, either gastric or intestinal, may lead to distinctive electrolyte abnormalities. In the former, metabolic alkalosis mandates repletion with chloride-rich replacement solutions (normal saline, usually with potassium chloride, as most patients are also hypokalemic). With intestinal losses of fluid, metabolic acidosis often ensues, and appropriate replacement may consist of a buffer solution of either isotonic bicarbonate or lactate-containing (Ringer) solution in combination with
Transdermal fluid losses usually occur in the setting of major burns, with the degree of hypovolemia and the severity of AKI corresponding to the extent of thermal injury (body surface-area involvement). Significant burns can lead to severe hypovolemia as a result of massive evaporative and exudative fluid loss across the damaged epidermis as well from redistribution of fluid due to edema in the injured tissues. This hypovolemia can stimulate a sympathetic nerve-mediated response with resultant renal vasoconstriction. In some instances, the severity of renal vasoconstriction, superimposed on hypovolemia, culminates in ATN. In addition, deeper thermal injury with skeletal muscle involvement may induce myoglobinuric AKI (see following discussion). Dermal losses of fluid are also seen in the setting of hyperthermia and heat stroke. The evaporative loss of sweat, which is hypotonic, leads to a hypertonic dehydration for most cases. Replacement with half-normal saline corrects free water and sodium deficits.

**Postoperative**

Postoperative AKI has long been recognized as a common complication of major vascular, abdominal, and open-heart surgery. The pathogenesis of postoperative renal dysfunction varies with the type of the surgery and the preoperative condition of the patient. AKI following abdominal surgery is often the result of translocation of fluid into the peritoneal cavity. In this phenomenon, third space losses cause intravascular hypovolemia and subsequent renal hypoperfusion. AKI is uncommon in patients undergoing routine abdominal surgery, but the risk is substantial in surgery for obstructive jaundice; this complication may develop in approximately 10% of patients. Major vascular surgery, particularly aortic repairs, is also frequently complicated by AKI, especially in the setting of a ruptured aortic aneurysm. Elective repair of an aortic aneurysm is seldom associated with AKI unless cross clamping is placed above the renal arteries. Although the definition of AKI and its incidence varies among studies, cardiac surgery appears to generate most of the cases in the acute care hospital. Cardiac surgery accounts for nearly two-thirds of the postoperative AKI. Repeated episodes of AKI and sepsis complicating AKI are associated with substantially higher mortality after surgery.

Several predisposing factors for the development of postoperative AKI have been identified, which can be used to stratify risk (Table 200.8). These include emergent surgery, an elevated preoperative serum creatinine, the use of an intra-aortic balloon pump, and combined coronary artery bypass graft and valvular surgery [10]. Still, it is often difficult to prospectively identify those patients at heightened risk for
perioperative AKI, especially since 40% of patients who develop AKI do not have frank perioperative hypotension or evidence of shock. Other factors appear to be important for the development of AKI. For example, aprotinin, an antifibrinolytic agent used until recently to decrease perioperative blood loss in cardiac surgery patients, tends to increase AKI and postoperative mortality [11]. Prolonged cardiopulmonary bypass appears to induce oxidative stress, embolism, and systemic inflammation, thus contributing to AKI [12]. Improved mortality and reduced incidence of AKI were observed with the use of “off-pump” technology in one large observational study [13]. Another randomized trial of 2,300 non-CKD patients failed to demonstrate a reduction in mortality or AKI requiring dialysis in the “off-pump” arm. However, the incidence of AKI was low in both arms of this trial [14]. Although a small, randomized trial of CKD patients showed improved renal outcomes in those undergoing “off-pump” surgery [15], more studies are needed to prove the benefit of this technology.

Minimum score, 0; maximum score, 17. Risk of development of AKI requiring dialysis increases with higher score. Frequency of AKI requiring dialysis for score of 0–2 point is 0.5%, 3–5 points is 2%, 6–8 points is 8%,
A number of methods have been used unsuccessfully to try to protect kidney function in patients undergoing surgery. Administration of “low-dose” dopamine has long been advocated for the prevention of AKI but has fallen out of favor due to the lack of efficacy. A large, randomized, prospective trial of preventive role of fenoldopam, a selective dopamine receptor agonist, was terminated early due to lack of effect on progression to dialysis or mortality and increase in hypotensive episodes in cardiac surgery patients [16]. Nesiritide, a recombinant human B-type natriuretic peptide, which increases diuresis, natriuresis, and afterload reduction, was studied in a double-blind, randomized trial of 300 patients with mostly preserved renal function undergoing coronary artery bypass graft surgery [17]. The use of nesiritide was associated with improved postoperative serum creatinine and reduced length of hospital stay as compared with the placebo. Nevertheless, a large, randomized trial in nonsurgery patients with acute decompensated heart failure (ADHF) showed little clinical benefit and worsening hypotension [18]. Several other strategies, including perioperative N-acetylcysteine (NAC) and mannitol administration, have not been shown to be effective for the prevention of postoperative AKI [19,20]. The use of calcium channel blockers, ACE inhibitors, or diuretics has been disappointing in this context as well [21]. In fact, perioperative furosemide use has been associated with detrimental effect on renal function after cardiac surgery [22]. Loop diuretics should be used only in patients with definite volume overload.

Prevention of postoperative renal failure still hinges on withdrawal of vasopressors as early as safely possible and maintenance of adequate perioperative intravascular volume. To date there is no definitive answer to what type of fluid is preferable for volume expansion. However, in the absence of hemorrhagic shock, the use of colloid hydroxyethyl starch is controversial and not recommended for volume expansion by KDIGO [23]. Identification of modifiable risk factors for the prevention of postoperative AKI is paramount. A retrospective study of 3,500 patients identified three potentially modifiable risk factors associated with AKI after cardiac surgery, such as preoperative anemia, perioperative RBC transfusions, and the need for surgical reexploration [24].

**Cardiogenic Shock and Acute Decompensated Heart Failure**

Our understanding of “cardiorenal syndrome” is evolving beyond the concept of low cardiac output causing renal dysfunction. We know that
approximately half of patients with ADHF have preserved left ventricular function [25]. In the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE), optimization of hemodynamics did not prevent AKI, further suggesting that reduction in cardiac output does not fully explain the development of impaired renal function [25].

A complex bidirectional relationship emerges, whereby heart failure and associated renal dysfunction affect each other. In addition to the traditional hemodynamically mediated AKI due to low cardiac output, the heart and the kidney are simultaneously affected by activation of the sympathetic nervous and renin–angiotensin–aldosterone systems. Such activation results in systemic vasoconstriction, salt and water retention, and volume overload, further exacerbating kidney dysfunction and heart failure. In addition, the immune system affects renal and cardiac function through monocyte-mediated endothelial activation, cytokine release, and apoptosis induction [26]. Furthermore, CKD, a risk factor for coronary artery disease, contributes to volume overload, diuretic resistance, and poor prognosis in CHF and ADHF [25]. Here, we will focus on acute ADHF with AKI as a common clinical problem in the ICU setting.

ADHF is frequently complicated by AKI. The Acute Decompensated Heart Failure Registry (ADHERE) of more than 30,000 patients with ADHF suggests that AKI has poor prognostic implications and predicts mortality in this patient group [27]. In one study, more than a quarter of patients with ADHF developed AKI as defined by a rise in serum creatinine of 0.3 mg per dL. However, even this relatively small rise was associated with 7.5-fold increase in hospital mortality [28].

Management of ADHF will be discussed in detail in Chapter 194. However, these patients are frequently diuretic resistant and hypotensive. The optimal diuretic dosing regimen remains undefined as a randomized, placebo-controlled trial did not show any difference between furosemide administered by bolus or continuous infusion [29]. Randomized trials of nesiritide, a recombinant B-type natriuretic peptide, failed to demonstrate a benefit of nesiritide for diuresis or preservation of renal function [18,30]. Tolvaptan, a vasopressin antagonist, has been studied in a large international randomized trial of more than 4,000 heart failure patients [31]. Tolvaptan was statistically better then placebo at improving dyspnea, edema, and weight loss but did not significantly improve the rate of death and rehospitalization for heart failure. The use of ACE inhibitors is often limited by AKI and hyperkalemia.

Other strategies for diuretic-resistant patients with ADHF include mechanical fluid removal with ultrafiltration (UF) or paracentesis. The use of UF in the ICU setting is discussed in detail in Chapter 201. Although early studies suggested benefit from mechanical UF, a randomized trial comparing diuretics and UF in patients with ADHF and
worsening renal function demonstrated no difference in diuresis but reduced renal function and more adverse events in those treated with UF [32–34]. Finally, elevated intra-abdominal pressures in ADHF may play a role in the pathogenesis of renal dysfunction [35]. The reduction of intra-abdominal pressure from approximately 13 to 7 mm Hg by paracentesis was associated with a reduction in serum creatinine from 3.4 to 2.4 mg per dL in diuretic-resistant patients.

**Severe Sepsis**

Sepsis is among the most common causes of AKI. The association between septicemia and AKI is confounded by the experience that renal dysfunction due to other causes is often complicated by infection. Although the incidence of sepsis in patients with AKI has been reported to be as high as 75%, only one-third of patients have clinically apparent sepsis at the onset of renal dysfunction.

AKI may develop in a setting of sepsis through multiple mechanisms. As discussed previously, inflammation appears to play a significant role. In animal models, sepsis can cause renal impairment even in the absence of hypotension [36]. Clinically, it is likely that endotoxin causes a reduction in GFR through hemodynamic mechanisms, including vascular pooling and renal vasoconstriction, which are mediated by local vasoconstrictors such as thromboxane and endothelin. Although cardiac output is often elevated in patients with sepsis, systemic vasodilation coupled with renal vasoconstriction can shunt perfusion away from the kidneys. Vascular pooling and third spacing generally necessitate volume expansion with isotonic saline. Because myocardial suppression, oliguria, and capillary leakage may accompany sepsis, it is essential to monitor the administration of fluids closely. A randomized trial of protocolized early resuscitation efforts in septic patients prevented incidence of AKI when the following goals were achieved within 6 hours of recognition of septic shock: mean arterial blood pressure ≥65 mm Hg, central venous pressure between 8 and 12 mm Hg, reduction of serum lactate levels, and urinary output ≥0.5 mL/kg/h [37]. Although mortality and renal outcomes were not improved by protocolized early sepsis management in recent, large, multicenter trials [38–40], they do support timely antibiotic administration and adequate intravenous fluid administration as cornerstones of septic shock treatment.

**Pancreatitis**
Pancreatitis may occur in association with various causes of AKI but can itself induce ATN and renal function predicts survival from acute pancreatitis. This is a rare phenomenon and is generally seen in patients with severe or hemorrhagic pancreatitis with serum amylase values of more than 1,000 units per L. Mortality may approach 70% to 80% in this setting, especially in those with multiorgan failure.

**Trauma**

AKI associated with severe trauma generally reflects the combination of acute volume depletion, hemorrhage, and myoglobinuria (see following discussion). Survival after trauma is markedly reduced when complicated by AKI.

**Abdominal Compartment Syndrome**

A variety of critical illness can lead to the intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS), such as intra-abdominal hemorrhage, peritonitis, third-spacing of fluid into the abdominal cavity associated with abdominal surgery, ileus, or pancreatitis, as well as overdistention with gas following laparoscopy. IAH is defined as an intra-abdominal pressure over 12 mm Hg measured by a bladder transducer on three separate occasions at least 4 hours apart. ACS is defined as an intra-abdominal pressure over 20 mm Hg, associated with one or more organ system failure [41]. The increase in intra-abdominal pressure leads to visceral ischemia, including AKI. The precise incidence of AKI resulting from ACS is unknown, but appears underreported [42]. Treatment usually requires urgent surgical decompression of the abdomen.

**Acute Bilateral Cortical Necrosis**

Acute bilateral cortical necrosis is rare. Unlike ATN, in which only tubular elements are involved, in acute cortical necrosis, glomeruli and tubules are destroyed by a process in which cortical vessels may be occluded with fibrin thrombi. Cortical necrosis usually occurs after profound hypotension. Approximately two-thirds of cases are related to obstetric complications, including abruptio placentae, pre-eclampsia and eclampsia, septic abortion, and amniotic fluid embolism. Nonobstetric cortical necrosis is most common in shock, sepsis, and disseminated intravascular coagulopathy, but isolated cases have been reported with snakebites, arsenic ingestion, and hyperacute renal allograft rejection. The pathogenesis of AKI in these conditions involves the hemodynamic insults of hypoperfusion and renal vasoconstriction and formation of
fibrin thrombi in the renal microvasculature. Typically, patients with bilateral cortical necrosis have anuric AKI. Although the diagnosis may be suspected early in the course of renal injury, ATN remains far more likely. When renal function fails to recover after several weeks, cortical necrosis may be confirmed by a renal biopsy. Other diagnostic tests are less specific. Renal scintigraphy most often demonstrates complete absence of isotope in the region of the kidneys. Computed tomography (CT) with contrast enhancement may demonstrate similar findings, indicating absence of perfusion to the renal cortex. Renal angiography shows patency of the main renal arteries and either a complete absence of cortical filling or a mottled nephrogram. Given the severity of the inciting disorder, mortality is high in acute cortical necrosis, with fewer than 20% of patients surviving.

**Nephrotoxicity and Drug-Induced Acute Kidney Injury**

Many cases of AKI in the ICU can be linked to the effects of endogenous and exogenous nephrotoxins.

**Myoglobinuria and Hemoglobinuria**

Rhabdomyolysis is often associated with leakage of myocyte contents, particularly the pigment protein myoglobin, into the plasma. Myoglobin, with a molecular weight of approximately 17,000 Da, is freely filtered by the glomerulus. In the distal nephron, myoglobin forms proteinaceous casts that obstruct urine flow. Myoglobin may also exert direct cytotoxic effects on tubular epithelium through the generation of reactive oxygen species.

Myoglobinuric AKI is a consequence of massive skeletal muscle injury of diverse causes. Traumatic rhabdomyolysis occurs in the setting of direct mechanical injury (crush syndrome), burns, or prolonged pressure. Myoglobinuric renal failure is an important cause of morbidity in virtually all wide-scale human catastrophes. Indeed, much of what is known about the syndrome derives from experiences with victims of wars and natural disasters. Crush injuries during the Armenian earthquake of 1988, followed by similar disasters in Japan, Turkey, Iran, and Pakistan, necessitated emergent mobilization of dialysis resources on a massive scale [43].

Nontraumatic rhabdomyolysis can occur with toxic, metabolic, and inflammatory myopathies, vigorous exercise, severe potassium and phosphate depletion, and hyperthermic states such as the neuroleptic malignant syndrome and malignant hyperthermia. Lipid-lowering drugs currently represent one of the most common causes of rhabdomyolysis. The use of heroin and amphetamines has also been reported in
association with rhabdomyolysis.

As with other forms of AKI, the prognosis depends largely on the gravity of the predisposing condition; AKI following massive trauma can be expected to run a longer course than that associated with nontraumatic causes. In particularly severe cases, oliguria and dialysis dependence may persist for weeks.

Clinical signs and symptoms of muscle injury, such as muscle tenderness, are absent in at least half of cases of significant nontraumatic rhabdomyolysis. The diagnosis is suggested by markedly elevated serum levels of muscle enzymes with serum creatine kinase levels usually higher than 5,000. The serum levels of phosphate and potassium are also typically elevated in rhabdomyolysis because lysis of muscle cells causes release of intracellular contents into the blood. A fall in the serum calcium is quite common. Rebound hypercalcemia often occurs during the recovery phase.

The therapy of myoglobinuria is similar to that of other forms of AKI, but there are several particular considerations. The tubular toxicity of myoglobin is enhanced when urine flow rates are low, urine is concentrated, and urinary acidification is maximal. It is therefore important in the early phases of the illness to ensure that the patient is in a volume-replete state and maintaining a rapid diuresis (i.e., urine output of at least 150 mL per hour). To this end, isotonic fluids may be administered. Most experts recommend the administration of bicarbonate-rich fluids to alkalinate the urine above a pH of 6.5 so as to improve the solubility of myoglobin. Diuresis may be enhanced with concurrent administration of loop diuretics. Some have argued that loop diuretics may introduce the potentially adverse effect of increasing urinary acid excretion and have advocated the use of osmotic diuretic agents such as mannitol. Mannitol, however, has the potential drawback of causing intravascular volume overload in patients whose kidneys may already have impaired urine output.

Hemoglobinuria can also result in AKI. The pathophysiologic mechanisms are similar to those involved in myoglobinuric AKI. Hemoglobinuric renal failure is relatively rare. Hemoglobin, with a molecular weight almost four times that of myoglobin, is less readily filtered. Furthermore, when hemoglobin is released into the plasma, it binds to haptoglobin, forming a bulky, nonfilterable molecular complex. Only when the haptoglobin-binding capacity is saturated (at plasma hemoglobin concentrations >100 mg per dL) does hemoglobin appear in the tubular fluid. Thus, only massive intravascular hemolysis, as may
occur with fulminant transfusion reactions, autoimmune hemolytic crises, and mechanical hemolysis from a dysfunctional prosthetic heart valve (Waring blender syndrome), can induce AKI.

**Radiocontrast-Induced Nephropathy**

The administration of intravascular radiocontrast agents leads to a syndrome of rapidly developing AKI. Contrast-induced nephropathy (CIN) is commonly defined as an absolute increase in serum creatinine of 0.5 mg per dL or a relative increase of 25% from the baseline within 48 to 72 hours of contrast exposure. The serum creatinine level begins to rise 12 to 24 hours and peaks approximately 4 days after the procedure. Some patients develop a transient increase in urine output as a result of contrast-induced osmotic diuresis, followed by oliguria. The majority of patients are nonoliguric and do not require dialysis. In patients who have undergone endovascular procedures, CIN must be differentiated from atheroembolic disease, which has a significantly worse prognosis.

Prospective studies report that the incidence of radiocontrast-induced kidney injury ranges from 1% to more than 50%. Much of this variance can be attributed to disparities in the definitions of AKI, the number of associated risk factors (particularly CKD), and the type of procedure performed. The incidence appears to be minimal in patients with normal renal function and without risk factors (see Table 200.9). Pre-existing CKD, however, particularly in patients with diabetes, confers a 6- to 10-fold increased likelihood of radiocontrast-induced AKI. Contrast-enhanced CT is associated with a lower risk of CIN as compared with coronary angiography. Noncoronary angiography had the highest incidence of CIN in a study of 660 military veterans, reaching 15% in patients with GFR less than 60 mL per minute per 1.73 m² [44]. In the ICU, the risk of contrast-induced AKI is likely much higher as patients often have concomitant nephrotoxic insults such as hypotension or sepsis.

There are several mechanisms by which radiocontrast-induced renal injury may develop. Hemodynamic factors are believed important, as contrast exposure causes initial vasodilation followed by prolonged vasoconstriction of the renal circulation. The finding of a low FE$_{Na}$ in some patients with contrast-induced AKI and the tendency toward rapid recovery suggest a role for reversible vasoconstriction. The intensity and duration of the vasoconstriction may be influenced by the underlying characteristics of the renal microcirculation. Endothelial factors that promote vasoconstriction, such as endothelin and adenosine, may participate in the pathogenesis of radiocontrast-induced nephropathy [45]. Other postulated mechanisms of radiocontrast-induced nephropathy include the generation of reactive oxygen species and the direct cytotoxic effect of the contrast media, especially with highly osmolar agents [46].

Since there is no specific treatment for radiocontrast-induced nephropathy, attention has focused on methods of prevention. Table 200.10 lists a number of preventative measures with possible benefit. However, the best preventive measure remains avoidance of radiocontrast and use of an alternative noncontrast imaging procedure if possible.

Since radiocontrast injury is augmented by hypovolemia, particularly in the presence of prostaglandin inhibitors, modest volume expansion and avoidance of NSAIDs are justifiable. Although isotonic bicarbonate, rather than saline, may reduce the risk of free radical injury, multiple randomized trials have yielded conflicting data [47–49]. Thus, there is no
consensus on optimal type, rate, or duration of infusion of fluid for prevention of CIN. For patients at risk (those with renal dysfunction or other risk factors), we use either 0.9% saline or isotonic bicarbonate bolus, 3 mL per kg over 1 hour before administration of contrast agent, followed by 1 mL per kg per hour infusion for 6 hours after procedure. The use of diuretics to augment urine output and manage intravascular volume may provide additional benefit [50,51].

NAC may ameliorate radiocontrast nephrotoxicity, possibly through an antioxidant effect. However, studies have produced conflicting results [52,53]. Though the benefit remains controversial, NAC appears to be a low risk intervention and is still frequently used. We typically give NAC 1,200 mg orally for two doses before and two doses after the contrast exposure.

Low-osmolality contrast formulations (600 to 800 mOsm per kg) have been shown to be less nephrotoxic than high-osmolar agents (>1,400 mOsm per kg) and are now commonly used in all patients. However, iso-osmolar agents, such as iodixanol, have not been shown to have a clear additional benefit as compared with low-osmolar agents [54,55] of patients undergoing contrast enhanced CT and coronary angiography.

Removal of contrast media by hemodialysis or hemofiltration to prevent CIN was studied in several small trials. A meta-analysis of these trials revealed no benefit and even suggested an increase in CIN with hemodialysis [56]. Similarly, there is no clear evidence to support hemodialysis or hemofiltration immediately after contrast exposure to preserve residual renal function in ESRD patients [57]. Therefore, the timing of dialysis after radiocontrast should be based on clinical judgment.

Studies of therapies directed against vasoconstriction have yielded disappointing results. A meta-analysis of theophylline and aminophylline, antagonists of adenosine receptors, showed no benefit in CIN prevention [58]. Fenoldopam, a vasodilatory analog of dopamine, and an endothelin receptor antagonist have been shown minimal or even deleterious effects on renal function after contrast exposure [59,60].

**Acute Phosphate Nephropathy**

Sodium phosphate, a hyperosmolar laxative, can cause AKI when administered orally or by enema [61]. Risk factors include CKD, volume depletion, and increased dosage. AKI typically occurs days to weeks after exposure and is likely caused by calcium phosphate precipitation with
tubular obstruction and injury. Kidney biopsy reveals calcium phosphate deposition in the tubules and interstitium, as well as interstitial inflammation and ATN [62]. The prognosis of APN is poor as kidney function rarely recovers completely and most patients are left with CKD or progress to ESRD.

With growing recognition of acute phosphate nephropathy, the FDA issued warnings regarding the risks of oral sodium phosphate preparations and many products were withdrawn, though some generic preparations remain on the market. However, these agents should be avoided as safer alternatives are widely available.

**Drug-Induced Syndromes**

Hospitalized patients, particularly those in ICUs, are exposed to numerous pharmacologic agents. Since many drugs are capable of inducing abnormalities in renal function, the appearance of AKI in any patient should prompt the clinician to investigate a possible drug-related cause. Drug-induced AKI has four major syndromes (see Table 200.11).

**Acute Tubular Injury**

Nephrotoxic medications often injure the renal tubular epithelium.
Tubular damage occurs with variable incidence through a variety of mechanisms including direct toxicity (aminoglycosides, tenofovir), osmotic injury (mannitol, intravenous immunoglobulin), and vasoconstriction (radiocontrast, NSAIDs). Tubular injury is typically reversible after withdrawal of the inciting agent, although recovery may take several days to weeks. Occasionally, specific renal tubular functional abnormalities, such as magnesium and potassium wasting, renal tubular acidosis, and impaired urinary concentration, may persist.

Volume contraction, pre-existing CKD, and liver disease enhance the risk of drug-induced tubular injury. The risk of nephrotoxicity is reduced by ensuring that patients are well hydrated before therapy. If possible, nonnephrotoxic therapeutic alternatives should be used in patients with underlying renal disease.

**Intratubular Micro-Obstruction**

A second form of acute nephrotoxicity is caused by drugs that precipitate in the renal tubules and urinary collecting system and obstruct the nephrons. Such agents are generally poorly soluble at low pH, as characterizes the distal tubular fluid. This syndrome has been reported in patients receiving relatively high-dose intravenous methotrexate and acyclovir, indinavir, low-molecular-weight dextran, and sulfamethoxazole. Prevention of micro-obstructive AKI necessitates optimal hydration of the patient and maintenance of a high urine flow rate. Urinary alkalization may be of benefit, depending on the nature of the obstructing agent. The syndrome is usually readily reversible and short lived.

**Acute Interstitial Nephritis**

Many medications can induce AIN, the syndrome of AKI with an inflammatory infiltrate in the renal parenchyma on biopsy (see Table 200.12). Originally associated with allergic manifestations such as skin rash, fever, and eosinophilia, more recent data suggests this clinical triad is relatively uncommon [63], especially in cases caused by NSAIDs. The risk of AIN is not dependent on medication dosage. AIN has a more variable course than syndromes of direct drug nephrotoxicity and cases may vary widely in the time of onset following exposure to the inciting agent (days to years), the severity of the renal injury, and the time required for reversal following withdrawal of the drug (days to months). In addition to hematuria and pyuria, the urine sediment may show a preponderance of eosinophils while heavy proteinuria is rare. White blood cell casts are a common finding (Fig. 200.2). The pathogenesis of AKI in this disorder is poorly understood. The renal histopathology early
in the course of the disease shows mainly interstitial infiltration with inflammatory cells, often (but not always) eosinophils.

Although steroids have never been shown to reduce morbidity in a controlled trial, most experts use them in severe cases of AIN (i.e., those in which supportive dialysis may become necessary). See the “Treatment” section for more details on management of AIN.

A variant form of AIN is occasionally encountered in patients who take NSAIDs, particularly fenoprofen, meclofenamate, tolmetin, and indomethacin. The hallmarks of allergy, drug rash, eosinophilia, and
eosinophiluria are absent. The urinalysis is nonspecific; some cases are marked by nephrotic range proteinuria. The renal pathology shows interstitial inflammation and normal-appearing glomeruli. As with classic allergic interstitial nephritis, this disorder regresses after cessation of therapy with the offending agent. Patients who have had this disorder should probably be considered at risk for recurrence with other NSAIDs.

**Hemodynamic or Autoregulatory Failure**

The final form of drug-related AKI pertains to drugs that cause abnormalities of glomerular blood flow. Two pathophysiologic subsets of hemodynamically mediated AKI may be identified, depending on whether the main action of the drug is on the afferent or efferent glomerular arteriole. When the medication increases afferent vasoconstriction, autoregulation of renal blood flow is impaired, and prerenal azotemia develops. This effect may be seen in association with NSAIDs, which reduce the synthesis of vasodilatory prostaglandins, or drugs that directly constrict the preglomerular vessels (i.e., vasopressors and possibly radiocontrast agents). When preglomerular vasoconstriction is severe and prolonged, frank ischemic tubular necrosis may result. More often, a rapidly reversible, prerenal form of AKI occurs.

The other subset of hemodynamically mediated, drug-induced renal failure is seen in association with ACE inhibitors, which block the formation of angiotensin II from angiotensin I. In addition to their role as antihypertensives, these are commonly used as afterload reducers for the treatment of congestive heart failure. When used in this setting, they may engender an improvement of renal perfusion, as reduced peripheral vascular resistance leads to reduced left ventricular impedance. Under conditions of attenuated and fixed renal blood flow, however (as would occur with bilateral renal artery stenosis), ACE inhibitors may cause a sharp reduction in GFR.

These syndromes are encountered almost exclusively in patients with significant underlying impairment of renal perfusion or function. Unless severe renal ischemia has occurred, renal function should rapidly return to baseline levels after withdrawal of the responsible drug.

**Renal Vascular Disease**

**Major Renal Vascular Disease**

Renal vascular disease is divisible into major vascular and microvascular syndromes. Major renal vascular disease is an unusual cause of AKI. Renal artery occlusion does not produce AKI unless it is bilateral or occurs in a solitary functioning kidney. The sudden appearance of flank
pain and a rising serum creatinine should lead the physician to consider acute renal artery embolism or thrombosis. The differential diagnoses in this scenario include nephrolithiasis, pyelonephritis (with or without urinary obstruction), and RVT.

Renal artery emboli occur most frequently in the setting of cardiac disease, particularly in patients with arrhythmias or mural cardiac thrombi. Frequently, multiple organs are involved, including brain, lung, and spleen. AKI is more likely to occur with a distribution of emboli to both kidneys, although azotemia may occur with a unilateral embolus.

If the thrombus or embolus involves a solitary functioning kidney, oligoanuria and a rising level of azotemia can be expected. In addition to flank pain and diminished urine volume, 50% of patients develop uncontrolled hypertension and 20% experience nausea, fever, or both in a large case series of patients with acute renal infarction [64]. The urinalysis is not specific. Leukocyturia, hematuria, and low-grade proteinuria have been found, as have a bland urine sediment. Radionuclide scanning often demonstrates patchy uptake of isotope or, in the case of total occlusion, no isotopic uptake. CT may demonstrate similar findings of diminished contrast uptake either by the whole kidney or localized wedge-shaped areas of nonperfusion.

Accurate diagnosis of renal arterial disease requires radiologic imaging. Renal artery duplex scan may reveal the absence of Doppler signal if total occlusion occurs, but provides only limited anatomical information if stenosis is present. The renal artery duplex is not as sensitive or specific for the diagnosis of stenosis as compared with angiography or magnetic resonance arteriography. Angiography provides the most accurate anatomic information, but it is also the most invasive test.

Occlusion of the renal artery does not inevitably lead to infarction. Particularly in patients with slowly developing atherosclerotic disease, collateral circulation via capsular or ureteric vessels may protect the kidney from infarction even though renal arterial blood flow is inadequate to maintain function. Surgery may be preferable in patients with renal artery thrombosis, although supportive care with anticoagulation has been the preferred treatment for renal arterial embolism. Reports of successful treatment with fibrinolytic agents (either urokinase or streptokinase) have led some to consider this the preferred treatment for renal artery occlusive disease, particularly in patients for whom surgery represents too great a risk.

**Renal Vein Thrombosis**

RVT is an uncommon cause of AKI. Bilateral renal vein occlusion occurs most commonly in severely volume-depleted children. In adults, it usually develops in the setting of nephrotic syndrome or renal cell
carcinoma, but can also occur with hypercoagulable conditions, sickle cell disease, pregnancy, use of oral contraceptives, or trauma. RVT generally does not cause AKI unless it is acute and bilateral or occurs in a solitary kidney. Flank pain and microscopic hematuria are the usual clinical manifestations in acute RVT. Duplex venography and CT scan can often establish the diagnosis and are less invasive than radiocontrast renal venography. Treatment usually consists of anticoagulation, although fibrinolytic therapy should be considered in patients with AKI and RVT.

Atheroembolic Renal Disease (Cholesterol Emboli)

Atheroembolic renal disease is increasingly recognized as a cause of AKI, but is probably still underdiagnosed. Atheroembolic disease is often found on postmortem examination. It is important to distinguish this syndrome from renal arterial thromboembolism.

Cholesterol embolization occurs only in patients with severe aortic atherosclerosis, usually after trauma to the wall of the aorta such as with aortography, major vascular surgery, or blunt trauma to the abdomen. Atheroemboli may also occur spontaneously, particularly in patients with diabetic macrovascular disease and those receiving anticoagulant therapy. Diffuse occlusion of the microvasculature by atheroemboli leads to tissue damage in either a subacute or an acute fashion. Patients may experience relatively minor abnormalities such as infarction of the tip of a single toe. Renal involvement is particularly common when diffuse embolization accompanies major arteriography or aortic surgery. Involvement of other visceral organs, including the pancreas, bowel, spleen, retina, and brain, may also occur. Typically, the cholesterol emboli form needlelike occlusions in small vessels, which then develop a chronic inflammatory response that can include the formation of a granulomatous reaction. Extensive infarction of bowel or sudden neurologic abnormalities may bring the patient to the ICU, where, in addition to the presenting findings, AKI is noted. In the kidney, occlusion of a sufficient proportion of the microvasculature results in varying degrees of azotemia. The azotemia may be sudden, after the precipitating event, or may develop more slowly and may follow a stuttering course marked by acute deterioration with intervening periods of incomplete recovery. The latter course helps to distinguish this diagnosis from that of radiocontrast nephropathy, which typically occurs within 24 to 48 hours after arteriography.

The diagnosis is often missed unless there are peripheral signs of
involvement such as blue distal digits or livedo reticularis of the lower extremities. A more subtle and less frequently observed physical manifestation is the finding of visible cholesterol emboli in the retinal vessels (Hollenhorst plaques). Less specific manifestations include peripheral eosinophilia and hypocomplementemia. The urine sediment is nonspecific.

Patients with atheroembolic renal disease experience the full spectrum of renal dysfunction, from minor degrees of azotemia to full-blown, irreversible renal failure. After an initial rise in serum creatinine, there may be an improvement in GFR over several weeks, probably attributable to nephron adaptation with hyperfiltration in remnant glomeruli. No specific management is available for atheroembolic renal disease. Management of renal failure, including dialytic therapy, may be indicated. Use of anticoagulants may worsen this condition.

Thrombotic Microangiopathies

Thrombotic microangiopathies (TMAs) are a group of disorders characterized by microangiopathic hemolytic anemia and thrombocytopenia often associated with multisystem dysfunction including AKI. TMA can occur as a hereditary or acquired hematologic disorder such as TTP and hemolytic uremic syndrome (HUS). It may also complicate systemic conditions including malignant and pregnancy-related hypertension, rheumatologic diseases such as systemic lupus erythematosis, scleroderma, and antiphospholipid antibody syndrome, various infections, malignancy, and disseminated intravascular coagulation. In primary TMAs, occlusion of the preglomerular and glomerular microvasculature by platelet microthrombi with reactive changes in the endothelium accounts for the rapid deterioration in renal function. Clinical and histopathologic features of malignant hypertension may also be seen.

TTP and HUS, which were previously thought of as the same entity with different clinical presentation, are now considered separate diseases based on different pathogenesis and are discussed in more detail in Chapter 109. TTP often presents with a pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, AKI, and neurologic abnormalities. In contrast to other forms of TMA, the AKI is often relatively mild. In TTP, diminished activity of a von Willebrand Factor (vWF) cleaving protein called ADAMTS13 generates abnormally enlarged vWF which leads to platelet activation and aggregation, microthrombi formation, and ischemia. Decreased activity or mutations of ADAMTS13 protein are observed in recurrent and familial forms of TTP. TTP can also be seen with certain infections, such as HIV. Several medications are associated with TTP, including clopidogrel, cyclosporine,
and chemotherapeutic agents, such as cisplatinum, bleomycin, and others.

In HUS, hematologic and renal features predominate, and ADAMTS13 activity is normal. HUS is associated with a variety of infectious diseases, such as enteric infections, particularly with *Escherichia coli* 0157:H7, Mycoplasma, Legionella, and Coxsackie A and B viruses. Clinical presentation of HUS has a diarrheal and a non-diarrheal form. In the diarrheal form, a Shiga-like toxin is postulated to cause AKI by entering the circulation, binding to the proximal tubular cells as well as arteriolar and glomerular capillary endothelium and causing inflammation and platelet activation. The pathogenesis of the non-diarrheal form appears related to abnormal activation of the alternative complement pathway leading to injury to the renal endothelium.

Treatment of thrombotic angiopathies varies greatly and will be discussed in detail in Chapters 91 and 92. TTP is a medical emergency and without treatment, mortality exceeds 90%. Prompt plasmapheresis and plasma exchange to provide the missing enzyme and to remove vWF cleaving protein inhibitor are essential and are often combined with glucocorticoids. Treatment of HUS is largely supportive. Renal management includes maintenance of adequate intravascular volume, avoidance of nephrotoxins, and dialytic support as needed. There is no proven benefit to plasmapheresis, but eculizumab, a monoclonal antibody directed against C5 has yielded excellent results in HUS related to complement activation [65]. Systemic diseases associated with TMAs are discussed in detail elsewhere in the text.

**Acute Kidney Injury in the Cancer Patient**

AKI is a relatively common complication in patients with neoplastic diseases. Many malignancies cause hypercalcemia which can induce AKI through alterations in renal hemodynamics (afferent arteriolar vasoconstriction and diminished GFR) and by causing volume depletion. In addition, long-standing hypercalcemia can cause nephrocalcinosis and CKD. The pathogenesis and therapy of hypercalcemia of malignancy are described in detail in Chapters 95 and 140. From a nephrologic perspective, the mainstays of therapy are volume expansion with saline supplemented with loop diuretics to enhance urinary calcium excretion, combined with measures to lower the serum calcium. In cases of severe AKI, dialysis may be needed to lower the calcium level. Of note, bisphosphonates used to treat hypercalcemia can also cause AKI through direct nephrotoxicity leading to ATN as well by inducing collapsing focal glomerulosclerosis [66].

The term *tumor lysis syndrome* refers to the sudden release of tumor cell contents often in response to induction chemotherapy. These
intracellular products include phosphate, potassium, uric acid, and other purine metabolites. They may cause diffuse tubular micro-obstruction once they enter the nephron, which results in sudden onset of AKI. The syndrome occurs almost exclusively in patients with hematologic malignancies, especially in the setting of large tumor burden and high cell turnover. Preventive measures include aggressive intravenous hydration to enhance urine flow and minimize precipitation of uric acid and calcium phosphate in the tubules as well as treatment with medications to prevent hyperuricemia. Allopurinol, which decreases the formation of uric acid, and rasburicase, which promotes the degradation of uric acid should be considered [67]. Febuxostat, which also lowers uric acid formation, may be more effective than allopurinol, but carries a greater risk of hepatotoxicity and is much more costly [68]. Alkalinizing the urine enhances uric acid solubility, but also may promote the precipitation of calcium and phosphate in various soft tissues including the kidney. To date, there are no studies showing improved outcomes with urinary alkalinization. A reasonable approach would be to limit hydration with bicarbonate-based solutions to patients with tumor lysis syndrome who also have a significant metabolic acidosis [69]. Of note, once the tumor lysis syndrome becomes established, the resulting oliguria and AKI may further complicate therapy. This requires a delicate balance between continued hydration and intermittent diuretics to maintain urine output and to avoid volume overload.

---

A number of commonly used antineoplastic agents have renal side effects and can cause AKI. Principal among these is cisplatin, which, like other heavy metals, can induce ATN. The incidence of this complication is less with the newer analog carboplatin. Saline loading of patients who are about to receive platinum-containing chemotherapeutic agents helps reduce the risk of AKI. High-dose (>2 g per day) methotrexate therapy can also cause AKI. The drug is primarily renally excreted and can result in tubular micro-obstruction from intraluminal crystallization of methotrexate metabolites. Raising the urine pH, substantially increases the solubility of methotrexate in the renal tubules. Thus, the cornerstone for prophylaxis relies on volume expansion with a bicarbonate based solution [70].

Many neoplasms involve the ureteric bed or periureteric lymph nodes. Obstructive uropathy must be considered in any case of unexplained AKI in an oncologic patient, particularly one with lymphoma, prostatic, colorectal, or cervical carcinoma. Such obstructions are usually readily detectable by ultrasonographic examination. If the sonogram fails to
detect hydronephrosis but obstruction is strongly suspected, further imaging should be done to determine the patency of the ureters. These tests may include CT Urogram, MR Urogram, and retrograde cystoureterography. One must carefully consider the patient’s GFR and their ability to receive various contrast solutions before selecting a test. In cases in which ureteral obstruction is confirmed, nephrostomy drainage is often required. Ureteral stents can be considered but may fail if extrinsic compression remains present. Regardless, such drainage measures may only be needed temporarily in tumors that respond sufficiently to radiation or chemotherapy.

Multiple myeloma is a neoplasm that is especially frequently complicated by AKI. Patients with this disease may develop renal injury from several mechanisms. Hypercalcemia is very common in myeloma. In addition, the paraproteins, particularly light chains (Bence–Jones proteins), can be directly nephrotoxic. Finally, filtered paraproteins can form occlusive casts within the urinary space (cast nephropathy).

Tumor infiltration of the renal parenchyma is an unusual cause of AKI, despite the frequency of metastases to the kidneys. Imaging studies should reveal kidney enlargement. Successful reversal with radiation or chemotherapy is unusual. Decisions regarding the use of dialysis in patients with widespread metastatic disease must be based on a realistic appraisal of the prognosis of the underlying disease and on the patient’s wishes.

Renal Dysfunction in Patients with Liver Disease

AKI frequently develops in the setting of advanced liver disease with prerenal azotemia being the most common form. Despite obvious fluid retention, these patients have decreased renal perfusion from reduced effective circulating volume due to splanchnic vasodilation, hypoalbuminemia, and various neurohumoral influences. The balance between controlling ascites and peripheral edema while avoiding prerenal azotemia is often difficult. Diuretic dose adjustments, judicious use of crystalloids, colloids, and blood transfusions may not be sufficient to prevent progressive loss of renal function. Patients with liver disease and AKI who do not respond to volume expansion are diagnosed with hepatorenal syndrome (HRS). Table 200.13 details a more specific definition of HRS [71]. HRS is usually seen in advanced cirrhosis, but it has also been reported in patients with acute hepatitis or hepatic neoplasm. Onset of the syndrome may be sudden or insidious.

| TABLE 200.13 Definition of Hepatorenal Syndrome [71] |
- Cirrhosis with ascites
- Serum creatinine >1.5 mg/dL
- No improvement of serum creatinine after 2 d with diuretic withdrawal and volume expansion with albumin. The recommended dose of albumin is 1 g/kg of body weight per day up to a maximum of 100 g/d
- Absence of shock, ongoing bacterial infection, current or recent treatment with nephrotoxic drugs, gastrointestinal or renal fluid loss
- Absence of parenchymal disease as indicated by proteinuria <0.5 g/d, microhematuria (>50 red blood cells per high power field) no abnormalities on renal ultrasound.

HRS can be considered a form of prerenal azotemia in patients with severe hepatic dysfunction that is refractory to volume expansion. The pathogenesis of the HRS is principally related to vascular changes induced by portal hypertension. Increased portal pressures cause the release of local vasodilators and splanchnic arterial vasodilation. This results in a drop in systemic perfusion pressure and compensatory activation of the sympathetic nervous system and the renin–angiotensin system which causes severe intrarenal vasoconstriction as depicted in Figure 200.4. HRS is initially a functional condition as evidenced by extreme renal avidity for sodium and water, suggesting AKI from hemodynamic changes rather than parenchymal injury. Furthermore, the process can reverse as involved kidneys function normally when transplanted into a recipient with intact liver function.
The vasodilatation in the splanchnic vascular beds that initiates HRS has been the target of several therapies. Albumin in combination with the vasoconstrictor terlipressin has been shown to be effective in randomized studies reversing HRS in the majority of cases [72,73]. However, terlipressin is currently not available in the United States. In patients under continuous hemodynamic monitoring, norepinephrine infusion combined with albumin has been shown to have similar outcomes to terlipressin with fewer ischemic complications [74]. In patients not in the ICU and where terlipressin is not available, treatment with midodrine and octreotide is recommended. Midodrine (7.5 to 15 mg orally three times a day) and octreotide (100 to 200 μg subcutaneously three times a day) is combined with albumin with the goal of increasing mean arterial blood pressure by 15 mm Hg [74–76].

Transjugular intrahepatic portosystemic shunts (TIPS) have not been well studied in cases of HRS. The limited data does show some improvement in renal function but this needs to be weighed against the increased risk of encephalopathy and procedural complication [77]. Finally, in patients with HRS with progressive loss of renal function, dialysis should be considered on a case by case basis [78]. In general, this modality is reserved for patients that are liver transplant candidates or who have reversible forms of hepatic failure.

Hepatic disease predisposes patients to ATN of the other causes (i.e., nephrotoxic drug exposure, radioccontrast exposure, hypotension, and sepsis). Patients with severe hepatic disease often have one or more of these risk factors. Furthermore, hyperbilirubinemia may predispose to AKI through the toxic actions of bile on renal tubules. Although the urinary sediment in most cases of ATN is distinctive with muddy brown granular casts, jaundiced patients without tubular necrosis may manifest pigmented granular casts simply as a direct result of the interaction of bilirubin with tubular cells. The diagnosis of ATN can be further complicated by the finding of a low $\text{FE}_{\text{Na}}$. Patients with ATN typically have a $\text{FE}_{\text{Na}}$ of greater than 2% as a result of tubular injury impairing sodium reabsorption. Because of the extreme nature of sodium avidity in
the setting of cirrhosis, patients may have a $\text{FE}_{\text{Na}}$ of less than 1% despite renal tubular injury.

Management of cirrhotic patients with sodium and volume overload is extremely challenging. Cirrhotic patients are in a tenuous physiologic state; they have little tolerance for small deviations, either positive or negative, from their optimal state of fluid balance. Sodium balance must be regulated with dietary restriction or diuretics, or both, if ascites and edema are to be controlled. When oliguria develops in patients with advanced cirrhosis, conventional therapy may fail to achieve adequate diuresis. High doses of intravenous diuretics, in combination or as continuous infusions, can be used. Since aldosterone appears to play a significant role in the sodium retention of cirrhosis, spironolactone may be a useful adjunct in diuretic therapy. Although patients with significant peripheral edema can often tolerate as much as a net diuresis of 3 L per day, those with ascites but no edema should be managed more cautiously to avoid AKI.

In patients with significant ascites that is refractory to diet and diuretic therapy, large volume paracentesis (LVP) can help alleviate abdominal pressure and reduce respiratory symptoms. Patients can have up to 5 L of peritoneal fluid removed safely with paracentesis, but simultaneous albumin infusions (8 g of albumin per L removed) should be administered in patients undergoing larger volume removal to avoid hypotension and possible AKI [79]. Although LVP does offer the convenience of rapid resolution of ascites, it does lead to protein loss and carries the risk of procedural complications. Peritoneovenous shunts, such as the Denver and LeVeen shunts, have been used to infuse ascitic fluid into the central circulation. In light of the high perioperative complication rate and the lack of data showing increased survival, the procedure is rarely used. Repetitive paracentesis remains the standard procedure to manage diuretic-resistant ascites.

The biochemical abnormalities that characterize AKI in the patient with hepatic disease are the same as those found in other settings, with a few special considerations. Owing to impaired hepatic synthesis of urea, these patients may have lower BUN levels than expected. In addition, these patients often have dramatically reduced muscle mass; thus, the creatinine level may be deceptively low despite advanced renal dysfunction due to decreased endogenous creatinine production. Azotemic patients with hepatic failure have increased metabolic substrate for ammonia production and therefore are at heightened risk for encephalopathy. Potassium depletion, a common electrolyte imbalance in

\[ \text{p. 1963} \]
\[ \text{p. 1964} \]
cirrhosis, further enhances ammonia synthesis. Since cirrhosis is often associated with diminished perfusion pressure, hyponatremia may develop in response to increased antidiuretic hormone (ADH) levels and decreased capacity to excrete free water. Patients with significant hyponatremia should have their water intake restricted to less than 1,500 mL per day.

Acid–base disturbances are common and varied in patients with advanced hepatocellular disease. Respiratory alkalosis can occur as a result of increased progesterone levels stimulating hyperventilation. The use of diuretics as well as the presence of secondary hyperaldosteronism can cause a metabolic alkalosis that can aggravate hepatic encephalopathy. As plasma pH rises, ammonium ions lose protons to the plasma; the resulting ammonia penetrates the blood–brain barrier more readily and can worsen encephalopathy.

Although the finding of metabolic alkalosis is common, acid–base disturbances can rapidly change in the cirrhotic patient. Patients with diarrhea may develop a nonanion gap acidosis. Or in patients with severe hypotension, a high anion gap metabolic acidosis related to lactic acid may develop. Lactic acidosis may be particularly severe in patients with liver disease because extraction and metabolism of lactic acid from the blood depend largely on hepatic function. In patients with a metabolic alkalosis, the subsequent development of a metabolic acidosis may be missed, as the bicarbonate may be in the normal range. This is a particularly treacherous combined acid–base disturbance because a near-normal serum pH may believe the true extent of the acidosis. As the acidosis worsens, the pH may plummet because of depletion of the bicarbonate buffer system, deficiencies of protein buffers, and inability to maintain adequate respiratory compensation.
DIAGNOSIS OF ACUTE KIDNEY INJURY

History and Physical Examination

In patients with no prior medical data, the history may be useful in establishing whether renal dysfunction is chronic or acute. For example, a patient with long-standing loss of appetite and pruritus is more likely to have CKD than AKI. In these cases, the background information often elicits evidence of previous renal or urinary abnormalities such as hypertension, proteinuria, or a history of diabetes mellitus. A thirsty patient, or one in whom daily weight loss has been documented, may have volume depletion causing prerenal azotemia. The avenues of fluid loss are usually identifiable. Exposure to nephrotoxic agents or a recent episode of sustained hypotension suggests the possibility of ATN. Symptoms of renal colic, abnormal voiding pattern, or a history of genitourinary malignancy point toward an obstructive cause.

The physical examination often furnishes some diagnostic information, particularly regarding volume status. Diminished skin turgor, sunken eyes, dry mucous membranes, the absence of axillary sweat, or orthostatic hypotension supports a diagnosis of prerenal azotemia. In disorders characterized by reduced effective circulatory volume, such as congestive heart failure and nephrotic syndrome, prerenal azotemia may exist in the setting of an expanded extracellular volume. Hypertension in patients with AKI should raise suspicion of intrinsic renal disease. The clinician must be alert for signs of systemic diseases that can cause acute renal injury, including vasculitis, endocarditis, and sepsis. Bladder distention and prostatic enlargement point to an obstructive cause. A full discussion of relevant history and physical findings for the different causes of AKI is beyond the scope of this chapter.

Urine Tests

The laboratory workup should commence with a urinalysis. The measurements of urine osmolality, electrolytes, and creatinine concentration are simple and useful, particularly in differentiating between ATN and prerenal azotemia. Urine specific gravity can be measured at the bedside while the results of the urine chemistry tests are pending. A high urine specific gravity generally correlates with a concentrated urine and is expected in prerenal azotemia, except in the presence of diuretics.

The familiar dipstick tests provide a readily available method for determining whether the urine contains protein or heme pigments. When
positive, they should raise the suspicion of intrinsic renal pathology. As
the dipstick test for protein measures only albuminuria, Bence–Jones
proteins will not be detected. Light chains can be detected by urine
protein electrophoresis or immunofixation. Daily urinary protein
excretion can be quantified by a 24 hour urine collection. Although
influenced by a number of potential confounding variables, the urine
protein to creatinine ratio from a random urine specimen rapidly
provides a gross estimate of the degree of proteinuria.

Formed elements in the urine sediment yield invaluable information
about the nature of AKI, particularly in intrinsic renal disease. The
significance of hematuria, pyuria, renal tubular epithelial cells, and casts
in the urine has already been discussed. The presence of RBC casts
distinguishes the hematuria associated with glomerulonephritis from that
of postrenal or urologic causes. Broad and waxy casts suggest that renal
disease is chronic. Virtually any lesion that can cause obstruction in the
genitourinary tract can produce hematuria. Crystalluria often occurs in
association with obstruction due to renal calculi or medications.

The \( \text{FE}_{\text{Na}} \) can indicate the degree of renal sodium avidity, which
generally reflects renal perfusion. A value of less than 1% typically
indicates prerenal azotemia. However, this test can be confounded by
concomitant diuretic therapy which will enhance urinary salt losses. In
these situations, the \( \text{FEUrea} \) can be used instead, since urea clearance is
unaffected by diuretics. The \( \text{FEUrea} \) is calculated via the same formula,
but substituting urea for sodium and a value of less than 35% is
suggestive of renal hypoperfusion (see Table 200.14 for additional details
[80]).

### TABLE 200.14 Formulas for Estimating Renal Function

**Fractional excretion of sodium (\( \text{FE}_{\text{Na}} \))**

The \( \text{FE}_{\text{Na}} \) is the proportion of the filtered load of sodium excreted:

\[
\text{FE}_{\text{Na}} = \frac{U_{Na}}{P_{Na}} \times \frac{P_{cr}}{U_{cr}} \times 100
\]

Urine sodium (\( U_{Na} \)) and plasma sodium (\( P_{Na} \)) are expressed as millimoles and urine
creatinine (\( U_{cr} \)) and plasma creatinine (\( P_{cr} \)) are expressed as milligrams per
deciliter.

**Cockcroft–Gault equation**

Creatinine clearance (\( C_{cr} \)) can be estimated by using the Cockcroft and Gault
formula which uses the patient’s age and body weight, where weight is expressed
in kilograms and plasma creatinine (\( P_{cr} \)) is expressed as milligrams per deciliter:

\[
C_{cr} = \frac{(140 \text{ – age}) \times \text{weight}}{(P_{cr} \times 72)}
\]

**Abbreviated MDRD equation** [80]
A series of derivations based on data from the MDRD study have yielded several equations that more accurately represent GFR serum creatinine concentration (SCr) measured in milligrams per deciliter.

\[
\text{GFR, in mL/min/1.73 m}^2 = 186.3 \times \text{SCr (exp}[-1.154]) \times \text{age (exp}[-0.203]) \times (0.742 \text{ if female}) \times (1.21 \text{ if black})
\]

**CrCl determined by 24-h urine collection**

CrCl can be estimated by collecting a urine sample for 24 h. This formula tends to overestimate the true GFR by at least 10% and some cases significantly more, as some of the creatinine in the urine is derived from tubular secretion.

Urine creatinine \((U_{cr})\) and plasma creatinine \((P_{cr})\) are expressed as milligrams per deciliter. \(U_v\) is 24-h urine volume in mL.

\[
\text{CrCl, mL/min} = \frac{(U_{cr} \times U_v)}{(P_{cr} \times 1,440)}
\]

GFR, glomerular filtration rate; MDRD, Modification of Diet in Renal Disease.

**Blood Tests**

The measurement of the BUN and creatinine is essential to identifying and monitoring AKI. As noted, the ratio of BUN to creatinine carries some diagnostic value, as a high value (>20:1) may indicate prerenal azotemia. Serial blood chemistries will help identify acid–base and electrolyte disturbances common with AKI. Anemia may suggest a more chronic form of kidney disease. Eosinophilia frequently accompanies AIN.

Specialized serologic tests may help answer specific diagnostic questions. The presence of antinuclear antibodies may suggest autoimmune nephropathy such as lupus nephritis or scleroderma, both of which may cause AKI. The serum protein electrophoresis or immunoelectrophoresis may aid in the diagnosis of multiple myeloma, which often presents as AKI of uncertain cause.

Estimates of GFR may be helpful in assessing the severity of AKI as well as for adjusting medication dosages. However, these formulas have limited utility in the early phases of AKI, since the calculations are based on the assumption that serum creatinine reflects a steady state. For example, the creatinine of a patient with AKI from complete loss of renal blood flow will take many days to rise to steady state even though the GFR is negligible from the outset. Estimates of GFR in the first few days will grossly overestimate the patient’s residual renal function. See Table 200.14 for equations used to estimate GFR.

**Radiographic Studies**
Various radiographic techniques may contribute to the evaluation of AKI. The abdominal flat plate (kidneys and urinary bladder) is an easily obtained study that can help establish the presence and size of both kidneys. If both kidneys are small, azotemia may be of a chronic nature. Radiopaque stones may be identified on abdominal plain films.

Renal ultrasonography, a safe, quick, high-yield procedure, is probably the first radiologic test that should be ordered in the evaluation of any azotemic patient. It permits the identification and measurement of both kidneys and is very sensitive for detecting obstructive uropathy (Fig. 200.5). (The specifics on performing point of care ultrasound examination can be found below.) Helical CT, with or without contrast, is a versatile and high-yield technique for establishing the size of the kidneys and recognizing hydronephrosis (Fig. 200.6), but contrast administered during the test can result in AKI in patients at increased risk such as those with renal insufficiency, hypovolemia, or multiple myeloma. Magnetic resonance imaging (MRI) offers similar data as helical CT but is less commonly used because of cost and availability. The use of gadolinium contrast should be avoided, if possible, in the setting of AKI due to the risk of nephrogenic systemic fibrosis.

FIGURE 200.5 Sonogram with right hydronephrosis. Kidney poles are marked by crosses. Dark, echolucent areas (arrows) in the center represent dilated collecting system.
Retrograde pyelography is reserved for patients in whom urinary tract obstruction is strongly suspected despite the inability to confirm this finding on other imaging techniques. It is generally performed in anticipation of relieving such obstructions as soon as they are identified, usually by placement of ureteral stents.

Isotopic renal scanning provides a safe means for locating the kidneys and allows estimation of their functional capacity. Radionuclide flow studies can be used to assess the rapidity of uptake of tracer by the kidneys. A delay in uptake helps to establish the diagnosis of impaired renal perfusion, whether due to structural renovascular disease or functionally impaired renal blood flow. Prolonged retention of radioisotope by the kidneys is suggestive of outflow obstruction. Radioisotopic scanning may be particularly helpful in assessing patients with prolonged AKI for the absence of blood flow and the possible diagnosis of cortical necrosis or renal infarction (Fig. 200.7).
Renal artery duplex scanning offers an alternative method of assessing renal arterial flow. Although noninvasive, the test requires significant operator expertise. In cases in which a higher degree of sensitivity and specificity is required, CT or MRI angiogram or even full renal arteriography may be necessary. Arteriography is more invasive but offers the opportunity for immediate therapeutic intervention such as angioplasty or vascular stenting.
Renal Biopsy

Renal biopsy is reserved for patients who are thought to have parenchymal renal disease. The indications for renal biopsy are a matter of some controversy, but the procedure should be considered when (a) azotemia is of recent onset and unknown cause; (b) there is a possibility that the patient has a renal disease that may require drug treatment (e.g., steroids or cytotoxic drugs) as with patients with probable glomerulonephritis, vasculitis, or AIN; (c) heavy proteinuria or nephrotic syndrome is present; or (d) the biopsy result might be of prognostic importance.
COMPLICATIONS AND TREATMENT OF ACUTE KIDNEY INJURY

General Principles of Treatment

The management of AKI is outlined in Table 200.15. These steps are applicable to any patient with AKI and are quite fundamental. Fluid balance should be measured during each 8-hour nursing shift with input/output recordings, and body weight should be recorded daily. Serum electrolytes and/or arterial blood gases may be needed daily or more frequently depending on the patient’s status. One of the most important principles is treatment of the underlying condition that led to AKI. Since renal injury is most often a consequence of another primary illness, correction of that condition is essential for renal recovery. The management of AKI remains largely supportive as clinical trials of a number of agents have yielded negative or inconclusive results.

</tbody>
</table>
Adjust doses of all renally excreted drugs
Withhold nonsteroidal anti-inflammatory drugs and angiotensin-converting enzyme inhibitors in patients with prerenal conditions
Avoid magnesium-containing drugs (e.g., antacids and milk of magnesia)

Nutrition
Restrict protein intake to ≤0.5 g/kg/d
Caloric (carbohydrate) intake of ≥400 kcal/d

Reduction of infectious risks
Remove indwelling urinary catheter in oliguric, nonobstructed patients
Strict aseptic technique and rapid removal, when feasible, of vascular catheters

Fluid Management

For patients with renal dysfunction, fluid management is often crucial because of decreased sodium and water excretion. The determination of fluid management should be based on a thorough physical examination as well as evaluation of daily weights, vital signs and net fluid balance. Although respiratory fluid losses are often minimal for patients on mechanical ventilation, insensible losses are significantly increased with high fever or dermal injury. Gastrointestinal fluid losses can be difficult to quantify. Daily weights are often the best means of assessing the net balance between intake and output. Additional data may be provided by measurement of central venous pressures or ultrasound assessment of intravascular volume.

In patients with pure prerenal azotemia attributable to hypovolemia, restoration of normal volume status is usually sufficient to return BUN and creatinine to their normal levels. A normotensive, volume-depleted, azotemic patient can receive up to 1 L of saline during a 4-hour period with the expectation that renal perfusion and urine flow will improve rapidly. Volume-depleted patients with hypotension should receive more aggressive fluid resuscitation, at least until their blood pressure normalizes and signs of hypoperfusion resolve. This maneuver is of diagnostic as well as therapeutic benefit because rapid response to the fluid challenge establishes that azotemia is due, at least in part, to prerenal factors. The estimate of isotonic fluid replacement should be based on the clinical findings. With orthostasis, it may be estimated that the patient is experiencing an ECF deficit of at least 10%. Fluid replacement in these circumstances should be administered regardless of
the patient’s urine output or the presumptive diagnosis of ATN as recovery of renal function can be hastened by early adequate volume repletion.

Hypovolemia may complicate intrinsic renal disease and urinary tract obstruction, superimposing a low perfusion state on the azotemia caused by these conditions. The finding of a low FE$_{\text{Na}}$ in a patient who previously had a high FE$_{\text{Na}}$ might indicate that, although tubular function has recovered, renal hypoperfusion persists. Fluid replacement should be given using isotonic saline.

In euvoletic patients, the following formula can be applied to estimate daily fluid requirement: daily fluid replacement (mL per day) = urinary + extrarenal + insensible losses, where insensible losses = 250 mL per day. For febrile patients, add 500 mL per day for every degree Fahrenheit more than 101. In edematous patients requiring volume removal, the rate of diuresis should be adjusted to avoid intravascular volume depletion which could exacerbate the AKI.

Diuretics are a mainstay of management in patients with volume overload and nonoliguric AKI. However, studies have shown no demonstrable improvement in patient survival when nonoliguric patients with AKI are treated with high-dose loop diuretics [81].

In addition, a meta-analysis of nine randomized furosemide studies to prevent or treat AKI failed to show a decreased need for dialysis or improved survival [82].

Despite the paucity of data regarding beneficial effects on renal recovery or survival, diuretics are essential for the maintenance of fluid balance in responsive patients. Loop diuretics are the principal agents and are given as intravenous bolus or through continuous infusion. Dose adjustments may be required to avoid decreased renal perfusion which could impair renal recovery or high dosages which have been associated with hearing loss and tinnitus [83]. Concomitant use of other diuretic agents that act at different segments of the nephron may enhance urine output. Patients with diuretic-resistant oliguria often require renal replacement therapy. This will be discussed in detail in Chapter 75.

Parenchymal Renal Disease

Although AIN usually responds to discontinuation of the culpable drug (see Table 200.12), the recovery may be protracted. The data on steroids in allergic drug-induced acute interstitial nephritis (DI-AIN) is mixed [84]. There are no randomized controlled trials and recommendations rely on case reports and retrospective data. Nevertheless, the use of
steroids appears to hasten recovery and reduce the likelihood of developing CKD [85]. Certainly, steroids should be considered for patients with DI-AIN associated with a significant reduction in GFR or for patients who do not promptly respond to withdrawal of the offending agent. These patients often require a renal biopsy to confirm the diagnosis. If steroids are used, the initial dose of prednisone is 1 mg/kg/d for 1 to 2 weeks followed by a slow taper over 1 to 3 months, depending on the response.

The treatment of various forms of glomerulonephritis is beyond the scope of this text. Briefly, in patients with AKI associated with proteinuria and hematuria, the diagnosis of glomerulonephritis should be considered. A renal biopsy may be helpful not only to aid in diagnosis but also as a means of predicting response to therapy. Patients with a sudden loss of renal function associated with nephritis may have “rapidly progressive glomerulonephritis” (RPGN). RPGN is broken down into three categories: pauci-immune glomerulonephritis, anti-GBM disease (Goodpasture), and immune complex mediated disease. The majority of these diseases require immunosuppressive therapy with steroids (high-dose intravenous corticosteroids consisting of 250 to 1,000 mg of methylprednisolone per day for 3 days or oral prednisone) in combination with a steroid sparing agent (cyclophosphamide, mycophenolate, or rituximab), and occasionally plasmapheresis. For example, the pauci-immune nephritides include Granulomatosis with polyangiitis and Microscopic polyangiitis both of which are initially treated with pulse steroids combined with either cyclophosphamide or rituximab [86]. In anti-GBM disease, pulse steroids, oral cytoxan and plasmapherisis are combined for maximal effectiveness. Plasmapherisis is employed to clear the plasma of formed antibodies (e.g., antiglomerular basement membrane antibodies) while the immunosuppressive drugs prevent the formation of new pathogenic antibodies [87]. Immune complex glomerulonephritides include a host of different diseases which require a variety of different approaches. Some of these diseases do not require renal-specific therapies, such as for postinfectious glomerulonephritis or glomerulonephritis associated with bacterial endocarditis. In the former case, spontaneous remission usually occurs; in the latter, antibiotic treatment of the underlying condition may result in clearing of the immune complex–induced renal lesion.

A number of different therapies have been proposed for the treatment of ATN. Dopamine at low doses dilates the interlobular arteries, afferent and efferent arterioles resulting in increased renal blood flow. However, clinical trials have not supported the efficacy low-dose dopamine infusion in the treatment of established ATN, and it is no longer recommended by nephrologists [88].

Fenoldopam, a selective dopamine-1 receptor antagonist which lacks
other α- and β-adrenergic effects, has also been proposed as treatment for AKI. A meta-analysis of 16 randomized trials of fenoldopam versus placebo or dopamine for prevention or treatment of AKI found that fenoldopam decreased the need for renal replacement and hospital death [89]. However, a recent, large randomized trial in cardiac surgery patients showed no renal protective effect [16]. Although fenoldopam is not currently recommended [88], further study will be required to fully clarify its role in AKI.

Clinical trials of atrial natriuretic peptide have shown modest improvements in outcomes for patients with AKI [90]. However, given the limitations of design and size of available studies, further investigation is needed to confirm the benefit of this agent in established ATN.

Treatment of Postrenal Failure

Timely relief of urinary obstruction is the goal of therapy for postrenal AKI. Acute intervention is mandatory in the presence of complete or bilateral urinary tract obstruction or severe metabolic or hemodynamic complications of AKI. Coexisting fever or any other evidence of urinary infection proximal to the obstruction requires a rapid decompression procedure to avoid bacteremic shock.

When bladder outlet obstruction is suspected, insertion of a bladder catheter should be attempted. If this is not possible, as is occasionally the case in patients with prostatic enlargement or urethral stricture, urethral dilation or percutaneous cystostomy should be performed. AKI due to upper urinary tract obstruction can be relieved by either the retrograde insertion of a ureteral catheter or by the percutaneous placement (under ultrasonic, fluoroscopic, or CT scan guidance) of a catheter into the renal pelvis.

Because of the defects in distal nephron function associated with high-grade obstruction, patients may develop hyperkalemia, hyperchloremic metabolic acidosis, and hypernatremia. Water and bicarbonate replacement are often required and can be administered as a solution of 5% glucose and water to which sodium bicarbonate has been added. The patient’s plasma volume and serum sodium should determine the tonicity of the administered fluid. If the patient is hypovolemic, an isotonic solution should be used. If the patient is hypernatremic, a hypotonic solution is needed. Hyperkalemia may respond to the institution of a diuresis that accompanies the relief of the obstruction and as well as correction of the acidosis.

A dramatic postobstructive diuresis often ensues after relief of urinary obstruction. This usually reflects mobilization of urine sequestered within the dilated ureterovesicular system as well as excess ECF retained during
the period of obstruction. As such, this postobstructive diuresis is considered appropriate to the pre-existing volume expansion. In some patients with correction of bilateral obstruction, a large diuresis and natriuresis may ensue, which result in hypovolemia and, sometimes, frank shock. The mechanism for this inappropriate diuresis is poorly understood but may involve release of a natriuretic substance. These patients require fluid replacement, usually with hypotonic saline, to repair the deficit and match urinary losses. A useful technique is to measure the urinary sodium and potassium concentrations periodically to determine the composition of the replacement fluid. However, care must be taken to avoid excessive fluid replacement as this will simply prolong the diuresis.

Abnormal Drug Metabolism

A complete survey of all of the patient’s medications should be made. Drugs such as NSAIDs or ACE inhibitors that may interfere with renal blood flow or GFR autoregulation should be discontinued. When possible, aminoglycoside antibiotics or other nephrotoxic drugs should be replaced with nonnephrotoxic agents. Contrast procedures should be avoided so as not to compound renal dysfunction in patients with acute or CKD. If this is not feasible, the risk should be minimized by taking prophylactic measures (see previous discussion). In addition, the dosage of drugs dependent on renal metabolism and excretion should be adjusted appropriately. Some drugs (e.g., aminoglycoside antibiotics and digoxin) are excreted almost entirely by the kidneys. If the dose or dosing interval is unchanged, reduced renal function leads to accumulation of the drug in body fluids and eventual drug toxicity. Other agents are hepatically metabolized, but the active metabolites are renally excreted (e.g., benzodiazepines). Phenytoin, independent of its excretion, may reach toxic concentrations because a larger proportion of the administered drug is displaced from albumin-binding sites in uremia. Drug doses need to be altered in most instances to account for residual renal function and the effect of dialysis on drug removal. It is important to remember that as the patient recovers renal function, upward adjustment of the dosage of renally excreted drugs is necessary. This subject is covered in detail in Chapter 202.

Nutritional Therapy

The management of nutritional therapy in the ICU is discussed in detail
in Section 20 (Metabolism/Nutrition). The guidelines for nutritional therapy in AKI are similar to those in other ICU patients. Patients with AKI are often catabolic and increase their production of nitrogenous products that require excretion. The degree of catabolism reflects the level of the patient’s metabolic stress and is, in turn, a function of the severity of the underlying illness. Protein and caloric requirements are much higher for patients with catastrophic illness and multiple organ system failure than for those with mild or moderate illness. Although caloric replacement needs to be adequate to reduce tissue catabolism, prevent ketosis, and meet the patient’s basal nutritional needs, the clinician must avoid providing excessive substrate for generation of metabolic waste products. This is particularly challenging for patients who are not yet being dialyzed; once patients are on dialysis, they are allowed more liberal fluid intake and can receive a greater intake of carbohydrates, protein, and fat, limited only by the rate of dialytic fluid and solute removal. As discussed in Chapters 212 and 214, the need for nutritional support is becoming an indication for renal replacement therapy [91].

**Hyperkalemia**

Hyperkalemia is the most immediately life-threatening electrolyte imbalance encountered in patients with renal disease (see Chapter 199). In AKI, hyperkalemia arises from the inability of the kidneys to handle the excretory burden of potassium. Sources of potassium should be identified and regulated appropriately. Potassium loads may be endogenous (e.g., tissue breakdown and hematoma reabsorption) or exogenous (e.g., diet, intravenous fluids, and medications). Even when the GFR is substantially reduced, the kidneys can excrete large amounts of potassium, provided that tubular secretion is intact. For this reason, hyperkalemia more often occurs in patients with parenchymal or postrenal AKI. Urine flow rate is an important determinant of tubular potassium secretion; therefore, oliguric patients are more prone to potassium imbalance than are nonoliguric patients. Many commonly used medications, including heparin, NSAIDs, and ACE inhibitors, can also inhibit tubular potassium secretion. These should be discontinued in hyperkalemic patients.

**Metabolic Acidosis**

The kidneys’ ability to excrete metabolically produced acids may be reduced, particularly in parenchymal and obstructive disease. Because acid excretion is primarily a tubular function, the degree of acidosis may not always correlate with the degree of GFR impairment. Indeed, pure tubular acid excretion abnormalities may exist independently of azotemia
(renal tubular acidosis). Metabolic acidosis that results from failure of the tubules to excrete hydrogen ions or conserve bicarbonate normally produces a hyperchloremic or low anion gap acidosis (see Chapter 198). When the GFR is severely impaired, retention of acid wastes may produce a high anion gap acidosis.

Bicarbonate supplementation in the setting of metabolic acidosis remains controversial as there are no studies demonstrating a beneficial effect of this approach. In addition, bicarbonate supplementation may cause volume overload and hypernatremia and may exacerbate hypocalcemia by lowering the ionized calcium level. However, systemic pH <7.1 is associated with a number of adverse hemodynamic effects including decreased myocardial contractility and impaired response to catecholamine pressor agents. Many clinicians empirically administer bicarbonate to maintain pH >7.1 [92].

Abnormal Salt and Water Metabolism

Although most fluids administered to patients are hypotonic, plasma osmolality normally remains within tightly fixed limits. The process by which plasma tonicity is preserved depends on the suppression of vasopressin release and the movement of free water in the ascending limb of the loop of Henle. This latter function is impeded whenever GFR is reduced, which results in water retention and hyponatremia. Conversely, some renal disorders are characterized by failure to conserve water. This situation, referred to as nephrogenic diabetes insipidus, is most common in tubulointerstitial disease and in partial obstruction of the urinary tract. Patients with these disorders are prone to dehydration and hypernatremia. The subject is covered in more detail in Chapter 199.

Abnormal Calcium and Phosphorus Metabolism

The ability of the kidney to excrete phosphorus normally is impaired when the GFR falls to approximately one-third of normal. High serum phosphorus levels lead to formation of insoluble calcium phosphate salts, which may precipitate in soft tissue. If the product of the serum calcium and phosphorus concentrations exceeds 70, precipitation in soft tissues becomes more likely. For this reason, administration of calcium to patients with AKI should be reserved for emergent situations, such as the appearance of tetany, seizures, or refractory hypotension. The tendency toward hypocalcemia with AKI may be additionally aggravated by the injured kidneys’ failure to form 1,25-dihydroxycholecalciferol, although vitamin D therapy is rarely required in cases of AKI.

Hyperphosphatemia is common in patients with AKI, particularly in patients with rhabdomyolysis or tumor lysis syndrome. Although there is no published data correlating the treatment of hyperphosphatemia with
improved outcomes, phosphate binders are typically initiated when phosphate levels rise to more than 6.0 mg per dL. The main phosphate binders available include calcium salts (calcium acetate and calcium carbonate), sevelamer, and lanthanum hydroxide. Unless the patient is hypercalcemic, calcium carbonate can be administered (1.0 to 1.5 g with meals) as the phosphate-binding agent. Although potent, aluminum-based binders are generally avoided because of concerns with aluminum toxicity.

### Uremia

Accumulation of endogenous toxins in the body eventually results in uremia. The uremic syndrome is a multisystemic symptom complex. The exact identities of the so-called uremic toxins are not known, although many possibilities have been suggested. Urea and creatinine are not uremic toxins but rather are markers of renal excretory capacity. One cannot deduce on the basis of urea nitrogen and creatinine levels exactly when a patient will become uremic. In general, the syndrome manifests itself at a GFR of less than 10 mL per minute.

Although uremia is considered an indication to initiate dialytic therapy, the syndrome may be insidious in onset and produce only vague symptoms. Lethargy, anorexia, nausea, and malaise, all of which may herald uremia, may well be attributed to extrarenal disease in the patient with AKI. Other, less subjective uremic manifestations constitute stronger indications for prompt initiation of dialysis, including bleeding diathesis, seizures, coma, and the appearance of a pericardial friction rub.

### Dialysis

The use of renal replacement therapy in AKI is discussed in depth in Chapter 201. Briefly, the decision of when to initiate dialysis is historically controversial. Patients with intractable volume overload, hyperkalemia, metabolic acidosis, or frank uremia clearly meet criteria for dialysis. However, many patients with significant AKI do not meet one of these criteria. This has led to a discussion regarding the merits of early or even “prophylactic” dialysis. The rationale for forestalling dialysis includes the invasive nature of the procedure as well as concern that renal replacement therapy can exacerbate hemodynamic instability that might prolong the course of AKI. There is also significant labor and cost associated with performing the procedure in the ICU. Nevertheless,
several observational studies appear to show decreased morbidity and mortality for patients initiated on early dialysis. It has been argued that early dialysis results in improved volume control as well as the clearance of a variety of cytokines and/or toxins that may be harmful. Unfortunately, at this time, there is still not adequate data to establish the optimal time to initiate dialysis. This issue is discussed in detail in Chapter 75.

Prognosis and Outcome of Acute Kidney Injury

AKI is associated with a substantial increase in hospital mortality, particularly for ICU patients whose mortality ranges from 40% to 70% [93–96]. The large range in mortality reflects the varied acuity of illness and case mixes in the reports. Patients with prerenal azotemia tend to have an excellent prognosis while critically ill patients with dialysis dependent ATN have had mortality rates that approach 70%. Despite medical advances, mortality in AKI has not improved significantly during the past 50 years [97] though may be due in part to increased acuity of illness of the patient population.

Patients with AKI clearly have increased mortality, but the degree to which this heightened risk is attributable to AKI as opposed to other comorbid conditions remains unclear. A number of published trials show that AKI is an independent risk factor for mortality [93,95,98]. The extent of the risk appears to correlate with the severity of the AKI with dialysis dependent patient being at the highest risk for death. It is not entirely clear how AKI impacts the risk of death, but it is known that patients with significant AKI have compromised immune systems and platelet function placing them at higher risk for complications.

At least half of all cases of AKI are nonoliguric. Nonoliguric renal failure is associated with improved odds of renal recovery and approximately half the mortality of oliguric AKI [99]. Most of these individuals do not have multiorgan failure, and their improved survival may be the result of a less severe primary illness.

The long-term renal prognosis of patients with AKI is impacted by several factors including the severity of the initial injury as well as baseline patient characteristics. Patients with brief ischemic events typically develop a mild form of AKI that often resolves within 72 hours with no long term sequela. Patients with prolonged episodes of ischemia or injury may have variable degrees of recovery [100–102]. A recent study compared 1,610 hospitalized patients with reversible AKI to a control group. At a medium follow-up of 3.3 years, the patients with a history of AKI had almost a twofold increased rate of CKD (hazard ratio 1.91) compared to controls [100]. For patients with severe initial renal injuries requiring dialysis, the risk of CKD may be as much as 20 times higher than those
with less severe injury [103]. In other studies, elderly individuals as well as patients with baseline CKD have been found to have a lower probability of full recovery [101,104,105]. Nevertheless, more than 80% of the patients who survive AKI will recover renal function and remain dialysis free [106].

Utility of Ultrasonography for Evaluation of Acute Kidney Injury

Ultrasonography is a primary imaging modality for evaluation of AKI, so it is an important component of competence in critical care ultrasonography.

Equipment

If available, a curvilinear probe designed for abdominal imaging is used (3.5 to 5.0 MHz). Alternatively, a phased array cardiac probe gives serviceable images when configured with abdominal presets.

Scanning Technique

With the patient in the supine position, the probe is placed in the posterior axillary line over the lower lateral chest wall in order to obtain a transcostal coronal plane view of the left right or left kidney in their longitudinal axis (Video 200.1). Useful landmarks for locating the kidneys are the liver or spleen, as the kidneys are adjacent and caudal to these organs. The inexperienced scanner often scans in too anterior a plane to locate the kidney. A useful rule to locate the kidney is to place the “knuckles on the bed” when the operator is positioned ipsilaterally and scanning the contralateral kidney. This results in an appropriately posterior scanning plane. Once identified, the probe is angled through the kidney in order to obtain multiple tomographic sections of its structure. The operator may rotate the probe counterclockwise by 90 degrees to obtain a transverse view of the kidney while angling through it to obtain multiple tomographic views.

The bladder is imaged by placing the probe just above the pubic bone in the midline. Using a transverse scanning plane, the scanning plane is angled in caudal direction in order to identify the bladder. Once identified, the probe is angled through the bladder in order to obtain multiple tomographic views of its structure. The operator may rotate the probe clockwise by 90 degrees to obtain a longitudinal view of the bladder while angling through it to obtain multiple tomographic views. Doppler analysis of renal blood flow has some applications for assessment of AKI, but requires training above the level typically needed.
by the frontline intensivist. If indicated, it is obtained on a consultative basis from the radiology service.

Ultrasonography Anatomy

See Video 200.1.

**Kidney Size.** The normal kidney size is 9 to 12 cm in length. Chronic renal disease results in reduction of kidney size. AKI may result in enlargement of the kidney size.

**Kidney Parenchyma.** The kidney parenchyma is formed by the outer renal cortex and centrally located medulla with contains the renal pyramids. The renal calyces may be prominently interposed between the pyramids; this is a normal variant. Normal parenchymal thickness is 1.0 to 1.8 cm, and is diminished in CKD. Normally, the renal parenchyma is hypoechoic when compared to the adjacent liver or spleen, and the cortex is slightly hyperechoic relative to the underlying medulla. Both AKI and chronic renal disease result in a hyperechoic parenchyma when compared to the adjacent liver of spleen. When comparing the echogenicity of the kidney parenchyma to the liver and spleen, the operator considers whether there is a disease process that may alter the echogenicity of the liver or spleen.

**Kidney Margins.** The outer boundary of the kidney is defined by Gerota fascia and perinephric fat. Normally, it is smooth. Persistent fetal lobulations result in distinct V-shaped indentations that are a normal variant.

**Pelvocalyceal Area.** The central pelvocalyceal area contains the collecting system, sinus fat, and the renal vasculature. It is hyperechoic and demarcated from the surrounding renal parenchyma. Chronic renal failure is associated with loss of demarcation between the pelvocalyceal area and the parenchyma. The normal collecting system is not visible. Obstructive uropathy results in dilation of the collecting system.

**Bladder.** The bladder is well imaged when filled with urine. The normal bladder is in midline location and is a symmetric organ with thin smooth walls. When nondistended, wall thickness is increased. The empty bladder may be difficult to locate unless a catheter balloon is inflated inside it. It may be difficult to distinguish a distended bladder with co-existing ascites. The operator searches for bowel structures within the
fluid filled structure; their presence indicates ascites. If uncertainty persists, injection of agitated saline into the bladder catheter with real-time imaging will generally resolve the issue.

Clinical Applications

Obstructive uropathy is a potentially reversible cause of AKI, so it is important to rule out this entity in the patient who has renal failure in the ICU. The examination can be performed in a short period of time, and is an essential part of competence in critical care ultrasonography (Video 200.2). It includes examination of both kidneys for hydronephrosis and bladder anatomy. The findings of hydronephrosis include dilation of the renal pelvis and calyces by urine with through transmission artifact. It can be classified as mild, moderate, or severe acute obstruction results in calyceal dilation that results in a dilation that ends with an acute angle point. In chronic obstruction, the calyceal dilation ends in curvilinear manner. In long-standing hydronephrosis, the renal parenchyma is thinned and the dilated collecting system comes to occupy most of the kidney profile. The presence of hydronephrosis is not necessarily associated with a reduction in urine flow. The obstruction may be unilateral, so one kidney continues to function; or it may partial, with sufficient pressure backup to harm the kidney but with continued urine flow.

Ultrasonography may identify the source of the obstruction, if it is in the collecting system of the kidney (e.g., kidney stones and malignancy). However, the ureter is difficult to reliably identify with ultrasonography even if dilated; CT scan of the retroperitoneum is the definitive imaging modality for this area. If the obstruction is at the level of the bladder, ultrasonography is useful to identify bladder tumors, blood clots, or prostatic enlargement as the cause for the hydronephrosis (Video 200.3). An occasional cause of anuria is a blocked bladder catheter. The presence of a catheter tip and balloon within the distended bladder indicates a blocked catheter that can be flushed clear. The presence of the inflated balloon within an empty bladder indicates a patent catheter if there is urine output, or an anuric patient if there is none.

The findings on ultrasonography of the kidney in patients with medical causes of renal failure are nonspecific (Video 200.4). The kidney may be enlarged with loss of the medullary cortical interface, and the cortex is typically hyperechoic in comparison to the adjacent liver or spleen. The examination is not useful in categorizing the etiology of the AKI. Chronic renal failure results in small hyperechoic kidneys with reduced parenchymal thickness, and loss of differentiation between the parenchyma and the pelvocalyceal area. In end-stage renal disease requiring dialysis support, the kidney may become so small and
hyperechoic that is difficult to locate with ultrasonography.

Limitations of Ultrasonography for Evaluation of AKI

1. **Identification of hydrenephrosis:** Obstructive uropathy may take up to 24 hours to manifest with hydrenephrosis; so it is appropriate to repeat the examination, if the clinical situation remains ambiguous. The patient with severe medical renal injury may have no urine production by the kidneys. This will obscure the presence of urinary tract obstruction because, with absent kidney function, there can be no hydrenephrosis in the unlikely situation where there is a dual diagnosis of severe medical renal failure and obstructive uropathy. Rarely, an infiltrative disease of the kidney (e.g., renal lymphoma) restricts enlargement of the collecting ducts in the presence of downstream obstruction.

2. Without advanced training in renal ultrasonography, the intensivist will regularly encounter abnormalities that are incidental to the main purpose of the ultrasonography examination, which is to determine whether there is evidence of obstructive uropathy. Where the operator identifies an abnormality of uncertain implication, they call for expert consultation with the radiology service. These include the following examples (**Video 200.4**).

   a. **Renal cyst:** Renal cysts are a common incidental finding that may be unilateral or bilateral. They are often located in the renal parenchymal at the poles of the kidney and occur in wide variety of sizes. Occasionally, they are in the pelvocalyceal area, and may be confused with hydrenephrosis. A simple renal cyst is anechoic with through transmission artifact, has no wall thickness, and is completely absent of internal echoes. Any other pattern requires radiology consultation.

   b. **Renal mass:** A renal mass is an occasional incidental finding. Regardless of size or location, this requires radiology consultation.

   c. **Renal stone:** Renal stones, if composed of echogenic material, appear as hyperechoic structures within the collecting system of the kidney. They may be single or multiple in number, and characteristically exhibit acoustic shadowing artifact. Ureteral stones are difficult to identify with ultrasonography. Renal stones in association with ipsilateral hydrenephrosis raise concern that there is a stone impacted in the ureter.

   d. **Renal abscess and pyelonephritis:** An intraparenchymal or perinephric abscess appears as complex hypoechoic mass with
irregular walls. Pyelonephritis does not have specific features on ultrasonography examination, with the exception of emphysematous pyelonephritis where there is a characteristic pattern of air collection within the kidney. If there is suspicion of renal infection on ultrasonography examination, radiology consultation is indicated.

e. **Bladder pathology** *(Video 200.3)*: Bladder mass is an occasional incidental finding that requires radiology consultation. Bleeding from the kidney or bladder may result in a thrombus that can obstruct drainage of the bladder. These may be difficult to differentiate from a bladder tumor. Bladder irrigation with removal of the thrombus is diagnostic. Bladder irrigation may be performed with real-time ultrasonography imaging to aid in clearing the thrombus. A large prostate may protrude into the bladder. Radiology consultation is required to further characterize any bladder mass.

f. **Difficulty with bladder catheter insertion**: If the insertion of a bladder catheter is difficult, it is useful to guide the insertion with real-time scanning. The site of the obstruction is usually an enlarged prostate. Ultrasonography allows the operator to avoid the complication of inadvertent inflation of the balloon within the prostate. This occurs when the tip of the catheter is in the bladder, but the deflated balloon has not been passed into the bladder. Urine flow is noted in the tubing, and the balloon is assumed to be in the bladder. The balloon is inflated thereby causing injury to the proximal urethra and prostate gland. With difficult bladder catheterization, the catheter and its balloon can be seen with real-time scanning within the lumen of the distended bladder before the balloon is inflated.

Renal Replacement Therapy in the Intensive Care Unit
MATTHEW J. TRAINOR • MATTHEW A. NIEMI • PANG-YEN FAN

INTRODUCTION

Rapid deterioration of kidney function in acutely ill patients is common and potentially catastrophic. Acute kidney injury (AKI) occurs in up to 70% of patients admitted to the intensive care unit (ICU) and is associated with a twofold increase in the already high mortality rate for this population. Medical therapy is often inadequate for the management of the metabolic disturbances and fluid overload that complicate AKI. In this setting, renal replacement therapy (RRT) is essential for the survival of the patient. In addition, patients with end-stage renal disease (ESRD) have high rates of hospitalization, particularly for cardiovascular disease and infections. These patients often require ICU care, including RRT.

Despite many technical advances over several decades of dialysis support experience, mortality remains alarmingly high (40% to 60%) for ICU patients with AKI. The high death rate is largely owing to the severity and the array of nonrenal organ system dysfunction, because mortality for patients with AKI is now primarily because of multiorgan system failure (MOSF). Accumulating evidence suggests that the consequences of AKI may in turn contribute to the injury of distant organs and that some forms of RRT may prevent MOSF [1].

The objectives of modern-day RRT now extend beyond correction of metabolic disturbances and volume overload to include facilitation of nutritional support and drug therapies, and even promotion of nonrenal organ system recovery. More proactive treatment strategies have resulted in a trend toward earlier initiation of dialysis. For example, with recognition that fluid overload increases mortality and that volume
control can improve outcomes [2–4], RRT is applied more aggressively to prevent volume overload.

An important principle of renal support strategies is that of “capacity (supply) and demand mismatch.” Critically ill patients have increased “demand” for renal function. Such patients often generate increased solute from their hypercatabolic metabolism and intensive nutritional support. In addition, they receive enormous amounts of fluid via medications, blood products, enteral and parenteral nutrition, and volume resuscitation. The stress of high solute and fluid loads may overwhelm the excretory capacity of even minimally injured kidneys. Furthermore, the limited “supply” of renal function from kidneys already compromised by AKI is further reduced by tenuous hemodynamics and endogenous/exogenous renal vasoconstrictor activity. RRT supplements the impaired ability of the injured kidney to match the high fluid and solute demand, thereby restoring balance [5].
PRINCIPLES OF SOLUTE CLEARANCE AND FLUID REMOVAL BY DIALYTIC TECHNIQUES

Dialysis therapies involve the movement of solute and plasma water across a semipermeable membrane separating a blood compartment and a dialysate compartment. For intermittent hemodialysis (IHD) and continuous renal replacement therapies (CRRTs), this process occurs within a cartridge called a hemofilter or hemodialyzer, as shown in Figure 201.1. For peritoneal dialysis (PD), the peritoneum serves as the semipermeable membrane separating blood in the mesenteric vasculature from the dialysate in the peritoneal cavity. Characteristics such as membrane thickness and pore dimensions determine the size and transfer rate of molecules that move between the blood and dialysate.

![Figure 201.1](image)

**FIGURE 201.1** Schematic diagram of a hollow fiber dialyzer. Blood enters the hemofilter, passes through hollow fibers, and exits at the opposite end. Dialysate enters through the side port, flows around the blood-filled fibers in the opposite direction as the blood, combines with ultrafiltrate, and exits via the side port near the blood entry port.

Removal of solute and water using RRT may occur by diffusion or convection. Diffusion (dialysis) involves movement of solute from areas of high concentration to low concentration. Solute molecules have kinetic energy and move in solution. They collide with one another and with water molecules, resulting in an even dispersion throughout the solution. When solute in motion encounters a membrane pore of sufficient dimensions, it moves through the membrane into the adjacent
compartment. Small molecules with greater molecular velocity are more readily cleared than are larger molecules even if both fit through the membrane pore. A high concentration of a solute in a given compartment favors a high frequency of membrane collisions and its passage through the pore. Water molecules will also pass easily through the membrane to the compartment with higher osmolality. In a static system, net transfer (dialysis) ceases when solute concentrations equilibrate in the compartments. For RRT, blood and dialysate are repeatedly replenished to maintain the high concentration gradients favoring efficient transfer of solute and water.

Convection involves the transfer of solute across a semipermeable membrane driven by a hydrostatic pressure gradient. Those solutes small enough to pass through pores are swept along with water by solvent drag. The membrane acts as a sieve, retaining molecules that exceed the pore size. All filtered solutes below the membrane pore size are removed at rates proportionate to their concentration. The convective removal of fluid in this manner is termed hemofiltration or sometimes ultrafiltration. This technique does not change the plasma concentration of small solutes (blood urea nitrogen [BUN], creatinine, electrolytes, and glucose), because water is removed in proportion to solute. In contrast, the concentration of larger molecules (albumin) and formed elements (hematocrit) increase as they are sieved off by the smaller membrane pores. Thus, the chemical composition of the filtrate (often referred to as ultrafiltrate) is almost identical to that of the plasma except for the absence of large molecules such as albumin.
OVERVIEW OF DIALYSIS MODALITIES

The general features of different dialysis modalities are summarized in Table 201.1.

CAPD, continuous ambulatory peritoneal dialysis; CCPD, continuous cycling peritoneal dialysis; CRRT, continuous renal replacement therapies; CVH, continuous venovenous hemofiltration; CVHDF, continuous venovenous hemodiafiltration; IHD, intermittent hemodialysis; SCUF, slow continuous ultrafiltration; SLED, sustained low-efficiency dialysis; UF, ultrafiltration.

**Intermittent Hemodialysis**

IHD is the standard form of RRT for the majority of stable patients with ESRD in the United States. In IHD, blood is circulated through a dialysis
machine and hemodialysis cartridge and then returned to the patient. Utilizing diffusion (principally for solute clearance) and convection (principally for ultrafiltration), this highly efficient modality provides rapid solute and volume removal but requires both specialized equipment and trained staff. Both blood and dialysate are pumped through the hemofilter at high-flow rates. The dialysate flow is countercurrent to blood flow to maximize concentration gradients throughout the course of the filter (Fig. 201.1). Diffusion of solute across the filter is bidirectional. Urea, creatinine, and potassium move from plasma to dialysate, whereas bicarbonate and usually calcium diffuse in an opposite direction (Fig. 201.2).

![FIGURE 201.2](image)

**FIGURE 201.2** Solute and water movement across the dialyzer membrane in hemodialysis and hemofiltration. Net effect on serum chemistries and hematocrit shown in box at right. A: Significant flux in solute with relatively small shift in water in hemodialysis. Postdialyzer chemistries significantly altered with small increase in hematocrit. B: Significant removal of water with concomitant removal of solute in hemofiltration. Posthemofilter chemistries unchanged, because solute is removed in proportion to plasma concentration; however, hematocrit is significantly increased because of high filtration fraction (see text for more detail).

Standard dialysis machines can also perform isolated ultrafiltration that results in fluid removal but does not significantly alter the chemical
composition of plasma. During ultrafiltration, the dialysis machine pumps only blood, but not dialysate through the hemofilter. This process generates a hydrostatic pressure gradient across the hemofilter membrane, resulting in convective fluid removal. However, no dialysate is used, so there is no diffusive solute clearance. Isolated ultrafiltration is typically used when volume overload is the sole concern.

Solute clearance can be adjusted by changing the dialyzer size and membrane; blood and dialysate flow; and dialysis time, as detailed later in this chapter. Fluid removal can be adjusted by changing the hydrostatic pressure gradient between the blood and dialysate compartments within the hemofilter, an automated process performed by the dialysis machine. Although this technique is commonly used in the ICU setting, the rapid shifts in solute and fluid can precipitate hemodynamic instability and may, therefore, be less suitable for critically ill patients. IHD treatments are typically performed for several hours three to four times per week. However, because the technique is labor and resource intensive, more frequent treatments may be limited by staffing and cost.

Peritoneal Dialysis

PD is the main form of RRT for approximately 5% to 10% of patients with ESRD in the United States. In PD, dialysate is instilled into the peritoneal cavity. Through diffusion, solute and volume enter the dialysate, which is periodically drained and replaced with fresh dialysate. Solute clearance is adjusted by altering the volume of dialysate or varying the duration of each “dwell” (the interval between dialysate exchanges). More frequent exchanges will enhance solute removal, provided there is sufficient time between dialysate instillation and drainage to permit diffusion across the peritoneum. Volume is removed by maintaining a high dialysate osmolality through a high concentration of dextrose. This osmolar gradient results in the movement of water into the peritoneal cavity and also contributes to solute clearance through solvent drag. Fluid removal is adjusted by altering the dialysate dextrose content.

PD can be performed as a series of manual dialysate exchanges done during the day (chronic ambulatory peritoneal dialysis or CAPD) or through automated exchanges utilizing a PD machine (cycler) typically done at night (continuous cycled peritoneal dialysis or CCPD). For CAPD, dialysate is changed every 4 to 6 hours with a longer overnight “dwell.” For CCPD, the exchanges are typically done every 2 to 3 hours through
the night, and the abdomen is often left empty or with only a small volume of dialysate during the day. PD is much less efficient than IHD but is better tolerated hemodynamically, because solute and fluid shifts occur gradually. In the ICU setting, PD is generally reserved for patients with ESRD who are already maintained by this modality. PD is generally not used for AKI because of technical difficulty in establishing dialysis access (discussed later in this chapter) as well as the low efficiency of solute clearance. Furthermore, instillation of 1 to 2 L of dialysate into the peritoneal cavity can impair respiratory mechanics, particularly in the setting of abdominal distention or ileus.

**Continuous Renal Replacement Therapies**

CRRT denotes several hemodialytic modalities that vary in their mode of solute removal and duration of treatment, but share the characteristic of slow solute and volume removal maintained over an extended period of time rather than high clearances over 3 to 4 hours as with IHD. Although less efficient than IHD, CRRT provides much higher clearances than PD. Like PD, these techniques are better tolerated hemodynamically than IHD, because solute and volume are removed gradually. These modalities are widely used for critical care patients, although they require intensive monitoring and necessitate ICU admission at a hospital with adequate resources and expertise. CRRT can be performed by a number of methods detailed later in the chapter. The operating parameters of different CRRT systems are summarized in Table 201.2. A schematic of the circuitry of the different techniques is presented in Figure 201.3.

Dialysate is pumped through the filter to generate diffusive solute clearance. D: CVVHD. The system utilizes high ultrafiltration with replacement fluid as well as dialysate. CRRT, continuous renal replacement therapy; CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; SCUF, slow continuous ultrafiltration.

Continuous Arteriovenous Hemofiltration, Hemodialysis, and Hemodiafiltration
Early forms of CRRT utilized arteriovenous (AV) systems that relied on the pressure gradient between the arterial and venous circulation to drive ultrafiltration across the hemofilter membrane. However, variations in arterial pressure led to inconsistent rates of ultrafiltration and solute clearance. AV systems also required the placement and long-term maintenance of large-bore arterial catheters at the femoral site. With modern double-lumen venous catheters and advanced pump-driven venovenous systems, these modalities have largely fallen out of favor.

**Continuous Venovenous Hemofiltration, Hemodialysis, and Hemodiafiltration**

In CRRT, solute removal is achieved by convection or diffusion or a combination of both. Continuous venovenous hemofiltration (CVVH) is a purely convective technique in which a pump system drives blood through the hemofilter and generates ultrafiltration rates of 1 to 4 L per hour. Blood flow rate is generally lower than with IHD, and dialysate is not used. Solute clearance is achieved by replacing these large volumes of ultrafiltrate with fluid that does not contain the solutes targeted for removal (e.g., urea and potassium). Solute clearance and volume removal are adjusted by altering the ultrafiltration rate and the rate of infusion of replacement fluid (RF). The administration of RF maintains fluid balance and lowers the plasma concentration of solute by dilution. RF can be infused before or after the filter along the course of the dialyzer circuit (Fig. 201.3).

In diffusion-based techniques such as continuous venovenous hemodialysis (CVVHD), a dual pump system drives both blood and dialysate through the hemofilter. Dialysate flow and blood flow rates are typically much lower than with IHD. The technique creates less ultrafiltrate (2 to 5 L per day) than CVVH, because the infusion pressure of the dialysate lowers the pressure gradient across the hemofilter membrane. As with IHD, diffusion of solute across the filter is bidirectional (Fig. 201.2). No RF is administered. In CVVHD, the flow of dialysate through the filter is countercurrent to the flow of blood, but the dialysate flow rate is significantly slower (1 to 2 L per hour = 17 to 34 mL per minute) than the blood flow rate (100 to 200 mL per minute). This disparity permits full equilibration of plasma urea across the membrane and complete saturation of dialysate.

For all forms of CRRT, solute clearance is directly proportional to the
effluent volume (Vef). Thus, Vef is a therapeutic target to ensure dosing adequacy, with effluent targets typically measured in mL/kg/h. The Vef is the product of the filtration process. It comprises the ultrafiltrate in CVVH, the “spent” (equilibrated) dialysate in CVVHD, and the combination of ultrafiltrate and spent dialysate in continuous venovenous hemodiafiltration (CVVHDF). Because urea is freely filtered in CVVH, its concentration in the ultrafiltrate is identical to that of plasma. Thus, 48 L of ultrafiltrate (effluent) represents 48 L of plasma fully cleared of urea. Similarly, in CVVHD, the effluent (spent dialysate) is fully saturated with urea. Each liter of spent dialysate reflects a liter of plasma fully cleared of urea. In diffusive systems, blood flow has little impact on clearance at low dialysate flow (1 to 2 L per hour) but increasing impact as dialysate flow increases.

CVVHDF combines diffusion and convection into a single procedure. Dialysate is infused at 1 to 2 L per hour to boost the convective clearance generated by high (1 to 2 L per hour) ultrafiltration rates. RF is needed to offset the high rate of ultrafiltration. Historically, CVVHDF was developed to overcome clearance limitations posed by the older generation of CRRT equipment, which limited both dialyzer blood and dialysate flow. However, current CRRT equipment delivers blood flow at 400 mL per minute and dialysate flow at up to 10 L per hour. Large bore (13 French [Fr]) catheters are increasingly used to support high-flow systems. These advances allow high-volume ultrafiltrate generation with less complex CVVH or CVVHD systems and have called the role of CVVHDF into question.

**Slow Continuous Ultrafiltration**

In slow continuous ultrafiltration (SCUF), a pump system maintains low blood flow (usually no more than 100 mL per minute) through a hemofilter and generates low rates of ultrafiltration (typically 100 to 300 mL per hour). This modality provides volume removal but does not alter the chemistry of plasma, because water is removed in proportion to solute. Compared with other CRRT modalities, SCUF is a low-intensity nursing procedure. The procedure is often used in settings of severe volume overload with acceptable chemistries.
TECHNICAL CONSIDERATIONS FOR RENAL REPLACEMENT THERAPY

Anticoagulation

Hemofilter fibers are prone to thrombosis, because removal of fluid through ultrafiltration leads to hemoconcentration at the distal end of the dialyzer. As the filtration fraction (FF), that is, the proportion of plasma flow that is filtered, increases, the risk of filter thrombosis also rises. The FF can be calculated as follows:

\[
FF = \frac{\text{ultrafiltration rate}}{\text{plasma flow rate}} = \frac{\text{ultrafiltration rate}}{\text{blood flow rate} \times \left[100 - \text{Hct}\right]}
\]

Thus, higher rates of ultrafiltration, especially when coupled with low blood flows, predispose to hemofilter thrombosis. Poor filter performance and filter clotting increases sharply at FF greater than 20%. Higher blood flow rates permit greater rates of fluid removal, because hemoconcentration within the filter is limited by the short transit time of blood through the dialysis cartridge.

IHD can generally be performed without anticoagulation. The high blood flows used with this technique permit adequate solute clearance and ultrafiltration with limited risk of dialyzer thrombosis. However, IHD without anticoagulation also necessitates frequent saline flushes through the hemodialyzer to help maintain fiber patency and, therefore, is more labor intensive than standard IHD. In addition, packed red blood cell transfusions cannot be infused through the arterial line of the dialyzer circuit, because the resulting increase in hematocrit will lead to hemofilter clotting.

However, with CRRT, blood flow rates are typically low and ultrafiltration rates high, especially for CVVH, and filter thrombosis is a significant barrier to effective implementation of these therapies, while also increasing nursing and equipment utilization and need for blood transfusions. One approach called predilutional hemofiltration involves infusion of RF into the CRRT circuit at a point before the filter, thus lowering the hematocrit through dilution. As a result, a higher ultrafiltration rate may be achieved without compromising filter life. However, prefilter RF also dilutes the solute concentration of blood entering the filter and reduces effective clearance. With this approach, the target Vef should be increased by 25% to compensate for the dilutional effect. Other CRRT parameters such as blood and ultrafiltration rate must be adjusted to compensate for this inefficiency.
Anticoagulation is generally necessary to maintain hemofilter patency with CRRT, especially for principally convective modalities such as CVVH. When heparin is used for anticoagulation, an initial bolus of 1,000 to 2,000 units is typically followed by a continuous infusion of approximately 10 units/kg/h, adjusted to maintain the partial thromboplastin time in the venous line of the blood circuit at 1.5 to 2 times control. However, heparin infusions do result in some systemic anticoagulation and may be contraindicated in patients with active hemorrhage or heparin-induced thrombocytopenia (HIT).

Despite theoretical advantages, low molecular weight heparins do not appear to offer any significant advantages in efficacy or safety over unfractionated heparin for RRT [6]. In addition, these agents are more costly and their anticoagulant effects more difficult to monitor.

For patients with active hemorrhage or high risk of bleeding, regional citrate anticoagulation limited to the CRRT blood circuit offers several advantages [7–9], and is the recommended anticoagulant for CRRT in patients without contraindications to citrate, according to the 2012 kidney disease improving global outcomes (KDIGO) AKI guideline [10]. Citrate infused in the arterial limb of the CRRT circuit prevents hemofilter thrombosis by chelating calcium, a critical component of the clotting cascade. Calcium chloride or calcium gluconate infused into the venous line of the system restores normal systemic calcium levels. This approach appears to reduce the risk of hemorrhage and extend hemofilter patency [11]. In addition, citrate can be used for patient with HIT.

Serum and ionized calcium levels must be carefully monitored when using citrate, especially in patients with significant liver dysfunction, and the calcium infusion appropriately adjusted. Citrate is hepatically metabolized into bicarbonate and can cause metabolic alkalosis. In the setting of hepatic failure, citrate accumulation results in elevated total serum calcium but low ionized calcium levels, reflecting increased circulating calcium bound to citrate. Trisodium citrate solution, typically used in this form of anticoagulation, may also cause hypernatremia.

Other methods of regional anticoagulation such as prostacyclin infusion or heparin reversal with protamine have been less successful. Prostacyclin, an arachidonic acid metabolite, has a half-life of only 3 to 5 minutes and inhibits platelet aggregation. However, it induces vasodilatation, is associated with hypotension, and is costly. Protamine binds and neutralizes heparin, but infusions are technically complex and may be associated with rebound bleeding.

Anticoagulation is unnecessary for PD. However, intraperitoneal fibrin can occlude the dialysis catheter. If fibrin clots are noted in the dialysate, heparin (1,000 units) should be added to each PD exchange for several days. Intraperitoneal heparin is not absorbed and will not cause systemic anticoagulation.
Blood and Dialysate Flow Rates

Maximal urea clearances with standard dialyzers require blood flows of approximately 400 mL per minute. However, when dialysis is initiated for ESRD, blood flow rates begin at 200 to 250 mL per minute and are increased incrementally over several sessions. The low blood flow limits the efficiency of the dialysis and prevents rapid solute and water shifts that can precipitate complications, including delirium, seizures, and dyspnea, collectively known as the dysequilibrium syndrome. With AKI, high blood flow rates (400 mL per minute) may be used immediately, unless the BUN has been markedly elevated for a prolonged period. Blood flow rates for CRRT can vary from 100 to 400 mL per minute, but dysequilibrium syndrome is not a concern because solute and fluid removal occur slowly compared to IHD. The dialysate flow rate typically ranges between 500 to 800 mL per minute in IHD. These rates are sufficiently high so that changes in dialysate flow have relatively little impact on IHD clearances. However, because dialysate flow rates are much lower with CRRT, increases in dialysate flow can significantly enhance solute removal.

Dialyzer Membrane

Most hemofilters are constructed as cylinders containing hollow fibers composed of semipermeable membranes with varying surface areas and pore sizes (Fig. 201.1). Pore diameters are sufficiently small to preclude movement of cellular material or albumin, while allowing movement of smaller and middle-sized molecules. The surface area of the membrane depends on the number and length of these fibers. In the case of a patient with an ingestion of a dialyzable substance, the use of a hemofilter with a larger surface area will enhance clearance. The initial hemofilter membranes, composed of cellulose, have been replaced by synthetic, more biocompatible materials, which cause less complement activation and leukocyte adherence.

Dialysate Composition

The production of dialysate begins with obtaining “ultrapure” water, which is necessary given the potential for backflow of endotoxin or bacteria into the patient. The standard composition of dialysates for both IHD and PD is summarized in Table 201.3. For IHD, chloride, glucose, and magnesium concentrations are generally fixed, whereas sodium,
potassium, calcium, and bicarbonate compositions are customizable. Sodium modeling, a strategy employed to prevent hypotension, consists of higher sodium concentrations at the start of dialysis, followed by a gradual reduction, to prevent hypernatremia. The higher sodium concentration helps to prevent rapid fluid shifts when urea is being rapidly cleared.

The dialysate potassium concentration generally ranges from 1.0 to 4.0 mEq per L, with 1.0 mEq per L dialysate generally reserved for cases of severe hyperkalemia. Use of 1.0 mEq per L dialysate is limited by its potential to cause arrhythmias owing to rapid potassium clearance.

The buffer used in dialysate is now uniformly bicarbonate. The concentration of bicarbonate in dialysate usually varies from 33 to 35 mEq per L. Higher bicarbonate concentrations (40 mEq per L) are used in severe acidosis or to offset elevations of carbon dioxide resulting from
the permissive hypercapnia that attends low tidal volume ventilation.

Dialysate calcium concentration in maintenance hemodialysis is 2.5 mEq per L of diffusible calcium. Because hypocalcemia is common in AKI and correction of acidosis may further depress ionized calcium, some experts advocate higher dialysate calcium concentration (3.0 to 3.5 mEq per L) in patients with AKI. High-calcium dialysate may be used to correct hypocalcemia but should be used with caution; animal models suggest calcium loading worsens organ dysfunction and mortality from sepsis [12].

For CRRT, a wide variety of dialysate and RFs may be used. The composition of dialysate employed in CVVHD may be identical to that of RF employed in CVVH. Potassium and calcium concentrations are selected to meet patient needs. Base composition may be bicarbonate or lactate or citrate. The latter two buffers are metabolized to bicarbonate and effectively address acidosis in most patients with adequate hepatic function.

The composition of peritoneal dialysate is relatively constant. These commercially produced solutions are available in 2- and 5-L bags and vary only in dextrose content (1.5%, 2.5%, and 4.25% concentrations). Icodextrin, a glucose polymer which is absorbed more slowly than dextrose, has been used for selected patients with severe hyperglycemia or poor ultrafiltration. If necessary, potassium, insulin, heparin, or certain antibiotics can be added to the dialysate.

**Dialysis Access**

Establishing and maintaining adequate access is paramount to the delivery of all types of RRT. Access is best considered in two distinct settings: the patient with ESRD with permanent access and the patient with AKI requiring temporary access.

**Arteriovenous Fistula and Arteriovenous Graft**

For the patient with ESRD maintained with IHD, permanent dialysis access options include an arteriovenous fistula (AVF), arteriovenous graft (AVG), or a tunneled central venous catheter (discussed later in this chapter). Created by connecting an artery to a vein, an AVF must “mature,” a process during which high blood flow causes gradual dilatation and thickening or “arterialization” of the veins proximal to the AV anastomosis. Once mature, the AVF can be repetitively cannulated several times a week for IHD. Considered the optimal access for IHD, an AVF provides high blood flow (>500 mL per minute), relatively low thrombosis rates, and low infection rates. However, AVFs require long maturation time (typically several months), making them unsuitable for
patients with AKI. In addition, AVFs cannot withstand continuous cannulation, precluding their use for CRRT.

For an AVG, a synthetic material is used to connect the artery and vein. Like AVFs, AVGs cannot be used to manage AKI, because they require several weeks to mature, and they cannot be used for CRRT. Compared with AVFs, AVGs are not as durable, have much higher rates of thrombosis and infection.

To preserve the patency of AVFs and AVGs, measurement of blood pressure, venipuncture, and constricting dressings or tourniquets should be avoided in the access extremity. Acute thrombosis may also occur in the setting of hypotension or severe volume depletion, two conditions common among critically ill patients.

**Peritoneal Dialysis Catheters**

Unlike IHD and CRRT, patients on PD do not require vascular access. Instead, PD catheters allow for infusion and drainage of dialysate from the peritoneal cavity. Most are made of silicone and have two synthetic cuffs, one placed beneath the skin and one beneath the abdominal fascia, which prevent displacement and infection of the catheter. Use of PD catheters is delayed for 1 or 2 weeks after placement to permit healing of the insertion site and catheter tunnel. In urgent situations, early use of permanent catheters can be attempted with low-volume exchanges and the patient supine, although this may increase the risk of dialysate leak or infection. Although very rarely used, when access is required for AKI, a noncuffed PD catheter can be placed at the bedside and used immediately. This procedure should be reserved for unique situations and be performed by a skilled operator because of the risks of bowel perforation or organ puncture.

**Hemodialysis Catheters**

For most patients with AKI, dialysis access is achieved by placement of a temporary central venous catheter. These devices fall into two different categories: acute noncuffed, nontunneled lines and long-term cuffed, tunneled catheters. All are of large diameter (12 to 15 Fr) and dual-lumen design. For patients with urgent or emergent need of dialysis, acute catheters provide rapid access for IHD and CRRT and are typically inserted at the bedside into the internal jugular or femoral veins. Complications of these catheters include infection, thrombosis, and
vascular perforation, as discussed below.

Cuffed, tunneled catheters are placed when the expected duration of dialytic support exceeds 2 weeks. Composed of soft material such as silicone, they are usually inserted under fluoroscopic guidance into the internal jugular, or femoral vein and exit through a subcutaneous tunnel. These dual-lumen devices are available in different configurations. For appropriate function, the catheters are placed so that the tips extend into the right atrium, thus permitting higher blood flows. Unlike the stiffer acute noncuffed dialysis lines, the softer cuffed catheters do not pose a significant risk of perforation. The subcutaneous cuff and insertion tunnel serve to anchor the catheter and also inhibit infection such that these lines may remain in place for several months or longer. Complications are similar to those with uncuffed catheters and are also discussed below.
INDICATIONS FOR AND TIMING OF INITIATION OF RENAL REPLACEMENT THERAPY

Remarkably, there is no consensus regarding the absolute indications for initiation of RRT in AKI. The absence of objective clinical or biochemical findings that universally warrant dialytic support have resulted in wide variation in clinical practice. A patient’s perceived mortality risk may carry as much weight as laboratory-based measures of kidney function [13]. Conventional indications for RRT include:

- Volume overload refractory to or with diuretic therapy
- Hyperkalemia or metabolic acidosis refractory to medical management
- Intoxication with a dialyzable drug or toxin
- Overt uremic signs or symptoms
  - encephalopathy
  - pericarditis
  - uremic bleeding diathesis
- Progressive and advanced asymptomatic azotemia

Reserving RRT for patients who meet one of these criteria may have little impact on the high mortality of AKI, particularly in the setting of MOSF. A treatment strategy that merely prevents uremic complications follows the old paradigm for AKI: these patients die with, but not of, their renal dysfunction. Despite recognition that AKI carries high mortality risk [14] and that aggressive management of RRT may affect outcomes and reduce mortality, no consensus guideline defines the optimal time to initiate RRT in AKI.

Early versus Late Initiation of RRT

The evidence for early initiation of RRT in AKI is summarized in Table 201.4. Studies are often difficult to interpret, because both timing of RRT initiation and intensity of RRT vary.

A recent retrospective study of Finnish ICU patients with AKI who were treated with RRT compared those who had conventional indications for RRT (“classic RRT”) versus those who did not (“preemptive RRT”), and further divided those with classic indications into “classic-delayed” or “classic-urgent,” depending on whether RRT was commenced within 12 hours of manifesting indications [15]. Nearly 44% of subjects received “preemptive” RRT, as defined by the authors. Ninety day–adjusted mortality was higher (odds ratio 2.05, $p = 0.04$) among the classic group. Within the classic group, a delay in RRT greater than 12 hours was also associated with a 3.85 odds ratio for mortality ($p = 0.01$). These observational data, therefore, suggest a survival benefit for earlier RRT.

A prospective study of over 1,200 ICU patients with AKI highlighted the nuances of the definition of “early” and “late” RRT initiation [16]. In this study, adjusted patient survival was superior when RRT was started at creatinine levels greater than 3.5 mg per dL, compared with lower levels. However, mortality increased with longer duration of time between ICU admission and RRT initiation. These results suggest the outcomes are not solely dependent on laboratory defined indications for RRT.

A recent single-center randomized trial of “earlier start” (BUN or creatinine of 70 or 7 mg per dL, respectively) versus “usual start” (determined by clinical judgment of treating nephrologist) dialysis for AKI demonstrated a trend toward significantly greater in-hospital mortality among the early-start subjects (20.5% vs. 12.2%). This difference, however, did not reach statistical significance for this outcome.
or for dialysis dependence at 3 months among survivors [17]. Contrary to the Finnish study cited above, these findings argue against a benefit from starting dialysis in an “early” or “preemptive” fashion in the absence of more conventional indications. Of note, a larger, multicenter study is currently underway to evaluate mortality among critically ill patients who start RRT immediately upon meeting laboratory and urine output-based criteria AKI, versus those who are monitored for additional “severity criteria” [18].

Multiple recent meta-analyses have summarized the evidence the timing of initiation of RRT. A 2008 publication analyzed 18 cohort studies involving more than 2,000 patients [19], for which a pooled 28% risk reduction in mortality was observed with early dialysis. A more recent systematic review and meta-analysis reported an odds ratio of 0.45 (95% confidence interval 0.28 to 0.72) for 28-day mortality with early RRT, in critically ill patients with AKI. In the latter review, early RRT may have also been associated with reduced RRT duration and ICU length of stay, and higher rates of renal recovery [20]. Both meta-analyses cite significant methodologic limitations that preclude definitive conclusions, including publication bias, variations in technology over the decades-long span of cited studies, heterogeneous definitions of early and late therapy, and a paucity of randomized trials.

Another major methodologic limitation of all observational studies is the omission of patients who never receive RRT from the analysis. Less than 15% of patients who meet RIFLE criteria (threelfold increase in creatinine) receive RRT during their hospitalization. Some patients with AKI recover renal function and survive, whereas others may expire before initiating RRT. Yet, neither outcome is integrated into a retrospective analysis. Among AKI patients managed with RRT, patients destined to recover and survive may enrich the early-start groups, whereas patients destined to die of MOSF after an extended ICU course may be overrepresented in late start groups. Future studies on early RRT versus late RRT, whether prospective or observational, must integrate a “No RRT” arm into the study design [21].

The best current guidelines for RRT initiation were formulated by the Acute Kidney Injury Network [22]. We summarize a similar list of indications in Table 201.5. Parameters for starting RRT should be considered within the context of the patient’s entire clinical condition. A specific indication may be absolute or relative. An absolute indication represents a stand-alone condition that makes RRT mandatory. A relative indication requires a concomitant condition without which RRT is not
mandatory but could be recommended. The presence of an indication in a relatively stable patient with oliguric AKI as single-organ system failure would be viewed differently from the same parameter existing in a critically ill patient with MOSF. The course of illness may be more important than absolute parameters. The strength of an indication for RRT depends on whether the patient’s clinical condition is improving or deteriorating or static.

### Dialysis Dose

There is no benchmark for the dose or intensity of RRT used to treat AKI. Many experts suggest that IHD in this setting should at least achieve the urea clearance recommended for patients with ESRD, although there are no data validating this approach. Urea clearance can be quantitated through the $Kt/V$ or urea reduction ratio (URR). The $Kt/V$ is a dimensionless index of dialysis dose for which $K$ is the urea clearance of the dialyzer, $t$ is the duration of dialysis, and $V$ is the volume of distribution of urea; the $Kt/V$ is thought to be a measure of time-averaged
urea clearance and is determined by applying predialysis and postdialysis urea and volume data to a published formula. The $Kt/V$ for each IHD should exceed 1.2, assuming single pool urea kinetics. Alternatively, some programs target a URR of more than 65% or 70%. The URR is calculated using the following formula:

$$\text{URR} = \frac{\text{predialysis BUN} - \text{postdialysis BUN}}{\text{predialysis BUN}}$$

RRT can also be used simply to maintain the BUN below a target level such as less than 80 to 100 mg per dL.

Methods of increasing urea clearance include maintaining high dialysis blood flows, often necessitating the use of large-bore catheters and high gauge needles, using larger dialyzers, and extending dialysis time or frequency. It is important to note that adequate urea clearance does not ensure that ultrafiltration needs are met and additional RRT may be required to address volume overload.

There is little data regarding the target dosage or intensity of PD for patients with AKI. Guidelines for patients with stable ESRD on this form of RRT remain incompletely validated, even for commonly used techniques such as CCPD. When employed in the ICU setting, the patient’s maintenance outpatient regimen is typically continued. However, adjustments such as increased exchange frequency, altered dialysate dextrose concentration, and, rarely, increased dialysate volume can be used to enhance solute and volume removal as clinically indicated.

Guidelines for the intensity of renal support in critically ill patients with AKI, particularly those on CRRT, were previously based on several single-center studies suggesting that more dialysis leads to better outcomes [23–25].

Today’s guidelines have been strongly influenced by a large multicenter US trial, the Acute Renal Failure (ATN) trial, which tested the hypothesis that more intensive RRT in critically ill patients would decrease mortality and promote recovery of renal function [26]. A total of 1,124 patients at 27 centers were randomized to intensive therapy (IT) and less intensive therapy (LIT). An integrated treatment strategy was used. Hemodynamically stable patients were managed by IHD, whereas unstable patients were managed with CVVHD or sustained low-efficiency dialysis (SLED). Patients were permitted to move from one modality to another as their hemodynamic status changed. For the IT group, IHD and SLED were performed six times per week, and CVVHDF provided an effluent flow rate of 35 mL/kg/h. For the LIT group, IHD and SLED were performed three times per week, and CVVHDF provided an effluent flow of 20 mL/kg/h. The 60-day mortality was no different (53.6% for IT and 51.5% for LIT). There was no difference between the two groups regarding duration of RRT, rate of recovery of renal function, or recovery from nonrenal organ failure. Another multicenter, randomized trial
conducted in Australia and New Zealand compared the effect of CRRT at two levels of intensity [27]. Higher intensity therapy did not reduce mortality at 90 days. Most recently, a multinational European trial revealed no differences in 28-day survival or several other pertinent endpoints, among patients with septic shock and AKI treated with high-volume or standard volume continuous hemofiltration at prescribed doses of 70 or 35 mL/kg/h [28].

Collectively, these studies do not imply that the dose of RRT is unimportant in managing AKI. Patients in the LIT group in the ATN study were better dialyzed than patients receiving usual care in typical clinical practice. Dialysis treatment (IHD or SLED) in the LIT group delivered a mean single pool $Kt/V_{\text{urea}}$ of 1.30 that generated a mean predialysis BUN of 70. Among patients managed CVVHDF, the median time for treatment was 21 hours per day, substantially longer than times achieved in clinical practice. We support the dosing recommendation of the ATN investigators, which are generally in line with recommendations put forth in the 2012 KDIGO AKI guidelines [10]:

IHD or SLED
- Provide hemodialysis three times per week (alternate days).
- Monitor the delivered dose to ensure delivery of a single pool $Kt/V$ of 1.20 or more.

CRRT
- Employ large caliber catheters and systems of anticoagulation to maximize filter life.
- Ensure effluent flow rate (hemofiltration rate + dialysate flow rate) of 20 mL/kg/h or more.
- In convective systems which employ RF, add 25% to the prescribed effluent flow rate (RF rate) to adjust for dilutional effects if prefilter RF is used.
MODALITY SELECTION

In the United States, the hemodynamically stable patient with AKI is generally managed with IHD. The technique provides rapid solute clearance and volume removal, but it is of limited utility in the setting of hypotension. Unstable patients are more often managed by one of the CRRTs. Patients may move from one modality to another with changes in hemodynamic status. Dialysis sessions are delivered at a minimum of three times per week. More frequent sessions are often required to achieve specific volume and metabolic targets. The average ICU patient with AKI receives 3.5 L of fluid daily. It is challenging, if not impossible, to mobilize this volume (24 L per week) over three IHD sessions alone. IHD may be supplemented with additional ultrafiltration sessions to meet volume needs.

The principal RRT options are IHD and CRRTs. PD management of AKI has declined markedly over the past 30 years, although it remains an important ICU modality in developing countries [29]; furthermore, a recent meta-analysis reported no differences of pooled mortality between patients with AKI treated with PD versus IHD or CRRT [30]. SLED is used by a minority of programs, often in response to resource considerations.

IHD Versus CRRT

Modality selection in AKI is highly variable and appears to be changing in favor of CRRT. Historically, most patients in the United States were treated with IHD. However, a recent survey of VA and US Academic Medical Centers reported a mix of IHD and CRRT modalities [31]. Internationally, CRRT is often the preferred modality for managing AKI [32,33]. The shift toward CRRT is driven by a number of important practical as well as some theoretical advantages for CRRT over IHD:

- CRRT induces less hypotension and is better tolerated by the patient with unstable hemodynamics.
- CRRT permits removal of large fluid volumes without inducing or exacerbating hypotension.
- Because CRRT induces less hypotension, it may promote renal recovery from AKI by avoiding repeated episodes of renal hypoperfusion.
- CRRT provides greater solute clearance than alternate day IHD.
- Because CRRT minimizes/limits hypotension and disequilibrium, it may
better preserve cerebral perfusion in acute brain injury and in hepatic failure. The convective clearance of CRRT, particularly CVVH, may remove harmful immunomodulatory substances in sepsis.

The major studies comparing IHD with CRRT are summarized in Table 201.6. Retrospective studies show no survival advantage of modality selection in AKI [34,35], and some report higher mortality among the CRRT–treated patients. Prospective randomized trials of different RRT modalities have reported variable results. Some studies suggest improved hemodynamic stability with CCRT [36,37], although none have demonstrated a difference in patient survival or recovery of renal function between CRRT and IHD.

In the largest and most rigorous prospective multicenter trial to date [38], 359 patients from 21 medical centers were randomized to IHD or CVVHDF. Severity of illness was similar among the groups. Pressor support was common at randomization (86% for IHD and 89% for CVVHD) as was sepsis (69% and 56%). Crossover from the IHD group to CVVHDF was low (3.3%), and both groups used the same dialyzer membranes. Sixty-day survival and recovery of renal function were identical among the groups. Unlike other prospective studies, this trial reported similar rates of hypotension. Hemodynamic stability among IHD patients was meticulously promoted by routine use of cool dialysate (35°C), very high dialysate sodium concentration (150 mmol), isovolemic connections, progressive ultrafiltration, and extended dialysis time (>5 hours). This study stands as evidence that most patients could be managed with IHD irrespective of hemodynamics, though it is worth noting that the mean IHD treatment time in this study was 5.2 hours.

A recent study of critically ill patients in a surgical ICU from Germany found no difference in mortality or intradialytic hypotension, between patients treated with CVVH and those treated managed with SLED, consisting of 12-hour dialysis treatments with blood flows of 100 to 120 mL per minute [39]. The SLED group had shorter duration of ICU stay and mechanical ventilation, as well as fewer blood transfusions. In addition, a cost analysis indicated that SLED required significantly less nursing time than CVVH.

Though several previous meta-analyses and systematic reviews concluded that no specific modality of renal support provides a survival advantage or increased freedom from long-term dialysis for patients with AKI [40–42], a recent meta-analysis did report higher rates of dialysis
dependence among AKI survivors initially treated with IHD [43]. Included with this analysis were two large studies [37,44] that demonstrated significantly higher dialysis dependence among survivors initially treated with IHD, although mortality was higher for patients managed with CRRT.

In summary, no evidence exists to support a survival advantage of a specific RRT modality in AKI. Some prospective trials suggest improved hemodynamic stability with CRRT, and some retrospective analyses suggest enhanced recovery of renal function. In many circumstances, modality selection is guided by medical and nursing expertise and by availability of equipment or nursing support. When both modalities are available, selection should be individualized according to clinical status. Most US tertiary care centers opt for CRRT in settings of hemodynamic instability. IHD can be used successfully in hemodynamically unstable patients, provided ultrafiltration rates are reduced by increasing the frequency and duration of treatment. Acute hemodialysis programs may be insufficiently staffed to perform high-frequency (five to six times per week) and/or extended (>5 hours) dialysis. The same staffing limitations have lead many US programs to extend the indications for CRRT to the patient with stable hemodynamics, but with severe volume overload and large obligate fluid intake.

Recommendations

We support the practice of most US centers and recommend CRRT over IHD for the management of AKI in the following clinical settings:

- Hypotension requiring pressor support
- Massive volume overload with high obligate fluid intake
- Highly catabolic patients who have failed to reduce BUN less than 80 mg per dL over three IHD sessions
- AKI in the setting of severe liver failure

Technical recommendations:

We favor CVVH because of its simplicity. There is no evidence that CVVH is associated with better outcomes than CVVHD or CVVHDF [45]. Regardless of the CRRT modality, the prescribed Vef should be 20 to 25 mL/kg/h.

Discontinuation of Therapy
Recovery of renal function is traditionally defined by the reversal of oliguria and progressive decline in serum creatinine. Increased urine volume may not be apparent in the nonoliguric patient. If the CRRT patient is intensively treated, the serum creatinine may be normal, making it impossible to detect a spontaneous decline. We define recovery of renal function according to the criteria used in the ATN study [26]:

Urine volume exceeding 30 mL per hour (720 mL per day)
6-hour timed urine collection to compute creatinine clearance:

\[
C_{\text{creat}} = U_{\text{creat}} \times \frac{\text{volume}}{P_{\text{creat}}} \div 360
\]

A comprehensive discussion of RRT complications is beyond the scope of this chapter. For example, complications of central venous catheter placement are discussed in Chapter 6. However, we review selected complications of dialytic support that are common in the ICU setting.

Infection

Infection is a common complication of all RRT modalities. For IHD and CRRT, infection is usually associated with hemodialysis catheter use and may result in interruption of RRT and increased mortality. The largest prospective randomized study comparing internal jugular and femoral catheters showed no difference of the risk for infection after 5 days [46]. This trial randomly assigned 750 patients to receive either jugular or femoral vein catheterization. The rate of catheter-related sepsis was the same for both groups (1.5 vs. 2.3 per 1,000 catheter days for femoral and jugular venous catheterization, respectively). Hematomas were significantly more common for jugular compared with femoral cannulation (3.6% vs. 1.1%). Thus, femoral catheters may be acceptable for short-term use.

Peritonitis is a common infectious complication of PD and is the leading cause of catheter removal and modality conversion. It typically results from bacterial contamination during the exchange procedure or migration along the catheter tunnel. Symptoms and signs include fever, abdominal pain and tenderness, and cloudy dialysate effluent. The peritoneal fluid white blood cell count of greater than 100 cells per mL with at least 50% neutrophils indicates bacterial infection; however, a lymphocyte-predominate cell count may accompany fungal or mycobacterial infections. When peritonitis is suspected, PD fluid cultures should be done prior to antibiotic therapy. *Staphylococcus aureus* and *Staphylococcus epidermidis* are common causes, however; polymicrobial and fungal infections should receive special consideration in the ICU. Patients with suspected peritonitis should receive empiric antibiotics to cover both Gram-positive and Gram-negative organisms, pending culture results.
Electrolyte and Acid–Base Disorders

All forms of RRT can cause a variety of electrolyte and acid–base disturbances. These are most common with CVVH, because convective losses of large volumes of plasma can easily lead to hypocalcemia, hypomagnesemia, hypophosphatemia, hypokalemia, and metabolic acidosis if RF and solute supplementation are not carefully adjusted. Measurements of serum electrolytes are needed at least daily and may be required more frequently in many clinical situations. With IHD and CVVHD, metabolic disturbances are less frequent, because the dialysate composition is adjusted to avoid excessive potassium removal and usually maintains calcium and magnesium levels while supplementing bicarbonate. Hypophosphatemia frequently complicates convective modalities such as CVVH, although it is less common with diffusive RRT.

Access Thrombosis

Thrombosis of vascular access is a frequent complication of RRT. AVF or AVG thrombosis often occurs in the setting of hypotension or severe volume depletion, particularly if there is stenosis of the venous system proximal to the access. AVGs are much more prone to thrombosis than AVFs. The diagnosis is usually obvious, because the access will no longer have a palpable thrill or an audible bruit. In cases of incomplete or impending thrombosis, cannulation of the access may reveal the presence of clots. Rarely, duplex ultrasound of the access is needed to confirm thrombosis. If possible, the access patency should be reestablished by either surgical thrombectomy or mechanical or chemical thrombolysis. The decision to repair or revise the AVF or AVG, as well as the approach used, will depend on the patient’s clinical status and the expertise and equipment available.

Less commonly, hemodialysis catheters can develop thrombus, typically manifesting as impaired blood flow through the catheter. A thrombolytic can be instilled into the catheter and allowed to dwell; if this fails to restore blood flow after multiple attempts, the catheter likely needs to be replaced.

Hypotension

Hypotension often complicates volume removal by IHD. Severe reductions in blood pressure during dialysis limit ultrafiltration, perpetuate renal injury, and compromise perfusion to other vital organs. The pathophysiology of intradialytic hypotension involves left ventricular (LV) underfilling and inadequate reactive (pressor) response to decreasing volume. The rate of ultrafiltration, the magnitude of fluid
shifts between the extracellular and intracellular compartments, and the plasma refill rate (as fluid moves from the interstitium to plasma) determine LV filling pressure. The risk of hypotension during IHD can be reduced by several methods:

- Reduce ultrafiltration rate by extending the duration of treatment
- Reduce ultrafiltration volume by increasing frequency of treatment
- Minimize intracellular fluid shifts by employing sodium modeling
- Potentiate vasoconstrictor tone by cooling the dialysate as low as 35°C
- Enhance plasma refill rate by infusions of albumin
- Promote vasoconstrictor tone with high dialysate calcium
- Promote vasoconstrictor tone with midodrine prior to dialysis
- Promote vasoconstrictor tone with norepinephrine or vasopressin

Chapter 202

Drug Dosing in Renal and Hepatic Failure: A Pharmacokinetic Approach to the Critically Ill Patient

BRIAN S. SMITH • SHUSEN SUN • KYLE FRAIelli • REENU NATHAN

Estimates of the incidence of preventable adverse drug events in the intensive care unit (ICU) range from 10 up to 40 per 1,000 patient-days [1,2]. Patients in an ICU are approximately twice as likely to experience an adverse drug event when compared with patients on a general medicine unit. This increased risk is likely a result of the greater number of medical problems faced by patients in the ICU plus their wider range of drug exposures. Critically ill patients are also at increased risk for developing renal dysfunction, because acute kidney injury (AKI) occurs in 7% to 50% of all adults admitted to an ICU and is associated with a several-fold increase in mortality risk [3–5]. Renal injury is also a risk factor for adverse drug events. As many as 45% of patients with an estimated creatinine clearance less than 40 mL per minute receive medications that are dosed as much as 2.5 times higher than the maximum recommended dosage [6]. In addition, adverse drug reactions occur in approximately 9% of patients with blood urea nitrogen less than 20 mg per dL versus 24% of patients with blood urea nitrogen greater than 40 mg per dL [7]. Adverse drug events not only place patients at increased risk for morbidity and mortality but also have a tremendous impact financially. It has been estimated that each adverse drug event increases hospital costs by $2,000 to $4,600 [8–10]. For all of these reasons, appropriate drug dosing for critically ill patients with kidney or liver injury is essential. The following review uses pharmacokinetic
PHARMACOKINETIC AND PHARMACODYNAMIC PRINCIPLES

To design an effective and safe medication regimen, a clinician must have a general understanding of a drug’s pharmacokinetic and pharmacodynamic characteristics and be able to adjust for changes in the drug’s disposition that occur with critical illness, AKI, and hepatic failure. Pharmacokinetics relates to the principles of drug absorption, distribution, metabolism, and excretion, whereas pharmacodynamics describes the pharmacologic response resulting from the drug at the site of action (receptor). Clinical pharmacokinetics is the application of knowledge of drug absorption, distribution, metabolism, and excretion to design patient-specific drug regimens with the goal of maximizing therapeutic outcomes and minimizing toxicity (Fig. 202.1).

Most drugs used for critically ill patients can be modeled using linear, or first-order, pharmacokinetics. This means that the drug is eliminated from plasma at a constant rate. As the plasma concentration increases or decreases, the amount of drug eliminated increases or decreases in a
directly proportional relationship. Clinically, if a drug dose is increased, the plasma concentration increases proportionally, as does the amount eliminated (Fig. 202.2). If a drug’s plasma concentration is plotted versus time using a logarithmic scale, two different slopes are evident (Fig. 202.3): The upper portion is known as the \( \alpha \) (or \textit{distribution}) phase, which represents the process of achieving equilibrium between the central and peripheral compartments. When monitoring serum drug concentrations, it is important to sample after the distribution phase is complete to avoid making decisions based on falsely elevated drug levels. The \( \beta \) (or \textit{elimination}) phase describes the section of the graph once distribution is completed. This phase represents drug elimination from the central compartment. The elimination rate constant (\( K_{el} \)) is obtained by calculating the slope of the line during the elimination phase, and it can be used to calculate a drug’s half-life (\( t_{1/2} \)).

**FIGURE 202.2** The effect of increasing daily dose on average steady-state drug concentrations for drugs undergoing nonlinear or zero-order pharmacokinetic modeling (solid line). The effect of increasing daily dose on average steady-state drug concentrations for drugs undergoing linear or first-order pharmacokinetic modeling (dotted line).
Some drugs, such as phenytoin, follow zero-order or nonlinear kinetics. *Zero-order*, or *Michaelis–Menten pharmacokinetics*, refers to removal of a constant quantity of drug per unit of time. As the plasma concentration of the drug decreases or increases, the amount eliminated remains the same. This is the result of metabolism by a saturated enzyme system capable of eliminating drug only at a constant rate, regardless of the serum concentration. Clinically, this means small increases in the drug’s dose can lead to large increases in the plasma concentration; hence, the term *nonlinear pharmacokinetics* (Fig. 202.2).
PHARMACOKINETIC TERMINOLOGY

The half-life of a medication is defined as the amount of time required for the concentration of the drug to decrease by 50% and is a function of drug metabolism and elimination. The half-life of a specific drug remains constant provided that the metabolizing and eliminating processes remain constant. If a patient’s renal or hepatic function declines, the half-life of the drug can be significantly prolonged.

The half-life of a medication can be used to determine the time required for a drug to reach steady state. Steady state is achieved when the amount of drug entering the body equals the amount eliminated, so plasma drug levels no longer increase. Steady-state conditions are achieved at a time approximately equal to four or five half-lives. A clinician should generally wait for steady state to be achieved before obtaining a drug serum concentration or changing medication dose. Knowledge of a drug’s half-life may help estimate how long it should take for a pharmacologic or toxic effect to clear. It is also important to be aware, however, that certain drugs (e.g., azithromycin) may be pharmacologically active longer than would be predicted from serum concentrations.

The rate of drug elimination from the body is described as the $K_{el}$. With first-order elimination, a constant percentage of drug is removed from the plasma per unit of time and is often expressed as minutes$^{-1}$ or hours$^{-1}$. The $K_{el}$ is also inversely proportional to the drug’s half-life. A drug’s $K_{el}$ and half-life are constants and do not change unless the metabolizing or eliminating processes (or both) change.

*Volume of distribution* is not a physiologic volume but rather a theoretical volume that relates the plasma concentration to the administered dose. It is easiest to explain the concept of volume of distribution by providing an example. If a 700-mg dose of a drug administered as an intravenous bolus to a 70-kg patient results in a calculated maximum plasma concentration of 7 mg per L, it appears as if the drug is dissolved in 100 L of fluid. The volume of distribution would be 100 L or 1.429 L per kg. Under normal physiologic conditions, however, a 70-kg adult does not have 100 L of body fluid. A large volume of distribution means that the amount of drug available to be measured in the plasma is reduced owing to distribution among peripheral compartments or binding to plasma proteins. Medications that are hydrophilic and remain in the central (vascular) compartment, and without high affinity for plasma protein binding, tend to have a lower volume of distribution with a value that is closer to the intravascular
volume. Drugs that are highly lipophilic and distribute to peripheral tissues, or are highly plasma protein bound, tend to have a very large volume of distribution.

Clearance describes the volume of fluid cleared of drug over time. Clearance through an organ is determined by the product of blood flow to the organ and the extraction ratio for the organ. The extraction ratio is the percentage of medication removed from the blood as it passes through the eliminating organ. It depends not only on the blood flow rate but also on the free fraction of drug and the intrinsic ability of the organ to eliminate drug.

Changes in blood flow to the organ responsible for clearing the drug or any factor altering the extraction ratio of a drug can alter a drug’s clearance. For example, a patient experiencing septic or cardiogenic shock may have impaired blood flow to the liver or the kidneys, hampering the clearance of a particular drug. In addition, if a pharmacologic vasopressor is added to the therapy, blood flow to the gastrointestinal tract may be compromised, resulting in a decreased absorption and transport of drug to the site of action.
RENAL DRUG EXCRETION

The primary organ of drug and drug metabolite clearance for most drugs is the kidney. There are three major processes involved in renal drug clearance: glomerular filtration, tubular secretion, and tubular reabsorption. Both critical illness and renal dysfunction can alter any of these pathways individually or in combination. Studies evaluating the effect of renal impairment on drug elimination typically examine changes in total body clearance or serum concentration, because it is difficult to determine the specific impact on each pathway individually if multiple clearance routes are affected simultaneously.

**Glomerular filtration** is the most common pathway of renal medication excretion. The glomerular filtration rate (GFR) for an average healthy adult is between 100 and 125 mL per minute and represents approximately 20% of total plasma flow to the kidneys. Many physiologic factors affect glomerular filtration, including hydrostatic pressure and osmotic gradients. For drugs whose primary route of elimination is glomerular filtration, excretion occurs at a rate that is directly proportional to GFR (first-order process). The degree of plasma protein binding also affects filtration because only unbound drug is sufficiently small in size to be filtered across the glomerular capillaries. To estimate the possible impact of decreased filtration, it is important for the clinician to be aware of the fraction of renal drug elimination, in addition to the excretion method for any active or toxic metabolite.

**Tubular secretion** refers to the active process of drug transport from the interstitial fluid surrounding the proximal tubule into the tubule’s lumen. The secretion rate depends on the intrinsic activity of the transporter, proximal tubule blood flow, and the percent of free or unbound drug. Tubular secretion can be an extremely efficient process with drug clearance rates exceeding filtration clearance [11]. Impaired renal function impacts tubular secretion because endogenous and exogenous organic acids and bases accumulate and compete for the transporters required for active secretion. It is difficult to predict whether secretion will be increased or diminished, which may ultimately lead to drug toxicity or reduced efficacy [12].

**Tubular reabsorption** of drugs can be active or passive. Most of the ultrafiltrate passing through the nephron is reabsorbed. As the volume of fluid in the tubule decreases with this massive reabsorption, there can be a dramatic increase in drug concentration in the tubule, which promotes passive diffusion from inside the tubule into the plasma. Manipulation of urine pH can be used to decrease drug reabsorption and, therefore, increase excretion. Urine alkalization enhances the elimination of weak
acids (e.g., barbiturates) by increasing the fraction of ionized drug.
PHARMACOKINETIC CHANGES IN CRITICALLY ILL PATIENTS WITH RENAL DYSFUNCTION

The pharmacokinetics of drugs used in critically ill patients can be altered as a function of the many dynamic physiologic changes that occur. Studies examining the pharmacokinetics of drugs used in the critically ill patient population are limited; most are performed in healthy volunteers or in relatively stable patients with a specific disease state. Patients with chronic kidney disease take multiple medications, and thus have an inherently increased risk of drug interactions, particularly in the context of altered pharmacokinetics associated with worsening renal dysfunction and critical illness. The next section of this chapter addresses some of the known pharmacokinetic changes and drug interactions that may occur in critically ill patients with renal impairment.

Absorption

Drug absorption in patients with renal dysfunction may be altered for many reasons. Gastrointestinal edema, nausea and vomiting as a result of uremia, and delayed gastric emptying all affect drug absorption in this patient population. In addition, patients may have comorbidities that contribute to changes in drug absorption, such as diabetic gastroparesis, diarrhea, and cardiovascular failure. Patients with chronic kidney disease and diabetic gastroparesis often are prescribed prokinetic agents (e.g., metoclopramide or erythromycin). The use of these agents may decrease enteral absorption of medications owing to decreased gastric transit time, leading to decreased therapeutic effects or delayed onset of action [13]. Patients requiring phosphate binding medications or antacids (aluminum or calcium salts) are at risk for having these medications chelate or bind to other medications and decrease their absorption. To minimize chelation, certain medications administered enterally, such as ciprofloxacin, need to be spaced around the dosing of antacid/phosphate binders by at least 2 hours [14]. Changes in gastric pH from antacids or other acid-suppressing medications may impair the dissolution process of other enteral medications, leading to incomplete drug absorption. Bioavailability studies are often lacking for critically ill patients, because
most are conducted in healthy adults. For a majority of medications, however, the bioavailability for patients with impaired renal function is unchanged or increased [15]. To avoid issues relative to uncertain bioavailability among critically ill patients, the intravenous route of administration is often preferred.

Distribution

The distribution of drugs with high binding affinity for plasma proteins can be significantly altered among critically ill patients with renal failure. Highly protein-bound drugs exist in a state of equilibrium between unbound (free) and bound drug (not free). Only the unbound drug is pharmacologically active. This means that if binding decreases, the amount of free drug available to exert a pharmacologic and toxic effect increases. Drug–drug interactions can occur when two highly plasma protein–bound drugs (>90% bound to plasma proteins) compete for the same plasma protein. If drugs such as warfarin, phenytoin, valproic acid, and salicylates (all highly bound to albumin) are administered together, displacement-mediated drug interactions may occur [16]. Drug binding interactions also occur among patients with poor renal function because of changes in the configuration of albumin. For example, the pharmacodynamic effects of phenytoin and warfarin are increased in patients with renal failure because of changes of albumin structure [17,18].

Critically ill patients often have reduced albumin levels because of malnutrition or the metabolic stress of acute illness (or both), and this can lead to higher free fractions of drugs and potentially increase the risk of toxicity. If a patient taking warfarin rapidly develops hypoalbuminemia as a result of critical illness, the result is an increased availability of free drug, resulting in an elevated international normalized ratio and potential risk for bleeding.

The volume of distribution for drugs administered to critically ill patients with renal failure can fluctuate considerably as fluid status changes. This can affect the clearance of drugs, and also protein binding, by altering the amount of free drug available to be metabolized or eliminated or both. Although it is very difficult, if not impossible, to predict these changes in drug distribution, it is important for the clinician to be aware of the risks and monitor for the signs of efficacy and toxicity so that the interactions are recognized and corrected.

Metabolism

The kidneys also actively metabolize medications, and impaired renal function can affect both renal and hepatic drug metabolism. Therefore, clinicians may adjust drug dosages to account for diminished renal
metabolism as well as decreased renal elimination [19,20]. Drugs that are oxidized by the cytochrome P450 2D6 isoenzyme are more likely affected than those metabolized by other isoenzymes [21]. The clinical significance of these effects in critically ill patients with renal disease remains to be determined, and the true relevance is difficult to define, because critically ill patients often have impaired metabolic function from nonrenal causes, including hepatic damage, diminished hepatic blood flow, and use of medications that act as enzyme inhibitors or inducers.

**Elimination**

The kidney is an important organ for drug and metabolite elimination; however, determining drug elimination for the critically ill patient population is challenging. Critically ill patients each have a unique combination of factors that can affect renal drug clearance.

AKI is often accompanied by metabolic acidosis and respiratory alkalosis, which may affect the ionization of drug molecules and, therefore, affect tissue redistribution and clearance. A low serum albumin is often associated with AKI and can lead to an increase in filtration of free drug and increased clearance of drugs that are normally highly plasma protein bound.

Dysfunction of other organ systems can significantly alter renal drug clearance through various mechanisms. For example, renal perfusion may be reduced by low cardiac output from a cardiomyopathy or acute myocardial infarction or by shunting of blood away from the kidney to the heart, brain, and muscle secondary to increased sympathetic nerve activity. Both of these mechanisms decrease drug delivery to the glomeruli, thus reducing the clearance of drugs that are eliminated primarily by glomerular filtration. Retention of fluid may increase a drug’s volume of distribution and further reduce drug clearance. States of profound vasodilation, such as sepsis, systemic inflammatory response syndrome, pancreatitis, and liver failure, may impair renal drug elimination by decreasing GFR. Patients with mechanical ventilation may have reduced cardiac output (owing to increased mean intrathoracic pressure), volume of distribution changes, and acid–base imbalance, which can also affect renal drug disposition.
ASSESSING RENAL FUNCTION

Assessment of kidney function of a critically ill patient is challenging but essential for appropriately dosing renally eliminated medications. GFR can be estimated from serum creatinine by equations that use age, gender, race, and body size as surrogates for creatinine generation [22]. However, GFR estimates remain imprecise, despite substantial advances in the accuracy of estimating equations based on creatinine during the past several years. The Cockroft–Gault equation is the most commonly used in the clinical and research settings. It estimates creatinine clearance rather than GFR and thus is expected to overestimate GFR. Appropriate clinical judgment should be exercised. The Modification of Diet in Renal Disease (MDRD) study equation is an alternative method and is the preferred equation for patients with chronic kidney disease [23]. It was derived from a study population with chronic kidney disease and underestimates the measured GFR in populations with higher levels of GFR. The MDRD study equation had greater precision and greater overall accuracy than the Cockcroft–Gault formula. The differences in calculated GFR between MDRD and Cockcroft–Gault equations will yield discordant dose adjustments in 12% to 36% of cases [24–26]. The clinician should be aware of the potential limitations of the currently available methods of GFR estimation and use clinical judgment to assess the level of renal function [27]. A more detailed discussion regarding the assessment of renal function can be found in Chapter 200. See Table 202.1 for drug dosing recommendations based upon renal function.

DIALYSIS

The clinician must often make decisions on medication dose adjustments for patients on renal replacement therapy despite a paucity of available information. It is, therefore, important to consider the dialysis system and drug characteristics that affect drug clearance, in addition to the degree, if any, of residual renal function. Failure to consider dialysis drug clearance may significantly reduce drug efficacy or result in toxicity. Detailed information regarding the many individual factors that must be considered to estimate dialysis drug clearance is discussed elsewhere [28,29]. Postdialysis replacement doses are usually necessary if clearance is particularly efficient, or residual renal function is significant. When drugs are given in multiple daily doses, at least one of the daily doses should be administered soon after the completion of dialysis. Drug dosing in peritoneal dialysis is not discussed here because it is not commonly used in critically ill patients.

Patients may benefit from therapeutic drug monitoring during medication therapy. Drug level monitoring is most useful for medications with established correlation between serum levels and drug efficacy or toxicity. Trough levels are generally drawn 0 to 30 minutes before the next dose is due for administration. Peak levels are usually drawn 1 to 2 hours after oral drug administration and approximately 30 to 60 minutes after parenteral administration to allow an appropriate period of time for tissue distribution (α phase). Peak levels are usually monitored 4 hours postdialysis for drugs with a high volume of distribution (e.g., digoxin) because tissue penetration of these medications is more extensive and, therefore, less of these drugs are available in the blood to be cleared by dialysis. As a result, the intercompartmental reequilibration postdialysis takes longer, so measurement of the level must be delayed to ensure an accurate result. Additional information regarding dialysis can be found in Chapter 201.
PHARMACOKINETIC CHANGES IN CRITICALLY ILL PATIENTS WITH HEPATIC FAILURE

The primary organ responsible for drug metabolism is the liver. Similar to renal disease, liver failure has the potential to significantly alter the pharmacokinetics of many drugs used in critically ill patients. Again, like renal dysfunction, liver failure may alter the absorption, distribution, metabolism, and elimination of a drug. There are limited data to help clinicians assess the impact of liver failure on drug metabolism and facilitate appropriate dose adjustments. Consequently, it is imperative for ICU clinicians to understand the pharmacokinetic and pharmacodynamic profiles of a drug in order to discern the potential effects hepatic failure and critical illness may have on the drug.

Absorption

Drugs administered via the enteral route are absorbed through the gastrointestinal lining, enter the portal circulation, and pass through the liver before entering systemic circulation. Some drugs are metabolized during this initial transit through the liver, a phenomenon known as first-pass metabolism or the first-pass effect. Critically ill patients with hepatic failure may have a reduced capacity to metabolize drugs, limiting the extent of first-pass metabolism. Patients with cirrhosis may have developed portosystemic shunts, further reducing first-pass metabolism effectively increasing the bioavailability of an enteraly administered medication. Medications such as morphine, midazolam, and labetalol undergo significant first-pass metabolism and may have increased bioavailability when given enteraly in this setting [30–32].

Distribution

Liver failure may alter a medication’s volume of distribution via a reduction in plasma protein synthesis (namely albumin and α-1 acid glycoprotein), development of ascites, edema, or a combination of these factors. The effects of reduced plasma protein binding on volume of distribution in critical illness have been discussed earlier in this chapter. The role of plasma protein binding on hepatic metabolism and elimination is discussed later in this chapter.
Metabolism and Elimination

Liver failure primarily alters the pharmacokinetics of a drug by a reduction in metabolism and elimination. Three major factors that influence the hepatic metabolism and elimination of drugs are enzyme activity, hepatic blood flow, and protein binding.

The two primary pathways responsible for the enzymatic metabolism of medications are phase I metabolism and phase II metabolism. Phase I metabolism involves oxidation, reduction, and hydrolysis reactions via the cytochrome P450 (CYP450) enzyme system to convert a drug’s parent compound to a metabolite. Phase II metabolism involves conjugation reactions to increase the water solubility of a parent compound or metabolite to facilitate renal elimination. In chronic liver disease, a reduction of hepatic cell number and activity may lead to a reduced ability to metabolize drugs. It is important to note that liver failure tends to reduce phase I metabolic pathways more than phase II metabolic pathways, although both can be reduced in advanced liver failure \[33,34\]. An example of this effect can be seen with midazolam and lorazepam. Midazolam undergoes phase I metabolism via CYP450 3A4, and lorazepam undergoes phase II metabolism via glucuronidation. Liver failure significantly reduces the metabolic clearance (phase I) of midazolam, but does not have a significant effect on the clearance (phase II) of lorazepam \[35\].

Critical illness has the potential to further alter both phase I and phase II metabolism depending on the disease state. For example, there is some evidence to suggest that hepatic metabolism of phenytoin may be increased after severe head injury \[36\]. Other conditions, such as burn injury, renal dysfunction, cholestasis, hypothermia, and some inflammatory states, have been shown to decrease hepatic enzyme activity \[37\]. Clinicians must also be aware of other factors that may influence CYP450 activity, such as genetic polymorphisms or drug interactions with the CYP450 system. Detailed discussion of the CYP450 system and drug–drug interactions is beyond the scope of this chapter.

The clearance of drugs by the liver is primarily determined by the extraction ratio and hepatic blood flow. The hepatic extraction ratio is the fraction of drug removed from the blood after one pass through the liver. The rate of hepatic metabolism of drugs with high extraction ratios (>0.7 or 70%) depends more on hepatic blood flow than cellular metabolism. Drugs with high extraction ratios include morphine and fentanyl. For example, if a critically ill patient is receiving intravenous morphine and
has a reduction in hepatic blood flow from septic shock, a reduction in morphine metabolism secondary to the reduction in hepatic blood flow is anticipated. Conversely, the rate of hepatic metabolism of drugs with low extraction ratios (<0.3 or 30%) depends more on cellular metabolism than hepatic blood flow. Medications with low extraction ratios include lorazepam, diazepam, and methadone [38,39].

Protein binding also has an important role for hepatic metabolism and the extraction ratio of a drug because only unbound drug is able to be metabolized. Plasma protein binding can be classified as nonrestrictive or restrictive. Medications that bind in a nonrestrictive fashion are easily dissociated from plasma proteins so that free drug is available for hepatic metabolism. Changes in protein binding for drugs exhibiting nonrestrictive binding have minimal impact on hepatic metabolism. Medications that display restrictive binding have a high affinity for plasma proteins, meaning less free drug is available for metabolism. If there is a reduction of plasma proteins during critical illness, there will be an increase in free drug available for metabolism, potentially resulting in an increased extraction ratio. This phenomenon is clinically relevant only for drugs with high extraction ratios.

### Estimating Hepatic Drug Metabolism

Although creatinine clearance can be a useful estimate for renal function for critically ill patients, there is currently no readily available, accurate, inexpensive method to quantify hepatic drug metabolism. Some studies have used scoring systems such as the Child’s Score or Child’s Score with Pugh Modification. While these scoring systems have been useful for assessing the severity of hepatic disease and predicting mortality, they do not accurately quantify the ability of the liver to metabolize medications and should be used cautiously in critically ill patients. In order to appropriately assess hepatic function as it relates to drug metabolism, a clinician must consider many factors, including laboratory data (bilirubin, albumin, and prothrombin time), clinical features (hepatic blood flow, protein binding, and ascites), other medications (drug–drug interactions), a medication’s pharmacokinetic profile (absorption, distribution, metabolism, and elimination), the pharmacologic properties of the medication (efficacy and toxicity), and available monitoring parameters (drug concentration and clinical responses). It is important for the clinician to use judgment when applying these dosing recommendations in clinical practice so that drug efficacy and patient safety is optimized. See Table 202.2 for drug dosing recommendations based upon hepatic function.

GASTROINTESTINAL DISEASE PROBLEMS IN THE INTENSIVE CARE UNIT
DOMINIC J. NOMPLEGGI
Acute gastrointestinal (GI) bleeding is a common emergency that often necessitates admission to the intensive care unit (ICU). There are compelling differences in incidence, clinical presentation, severity, and mortality between lower and upper GI hemorrhage. The annual incidence rate of lower intestinal bleeding is estimated at 20.5 to 33 cases per 100,000 adult populations [1,2], whereas that of upper GI bleeding is estimated between 60 and 125 cases per 100,000 [3,4]. The incidence of upper GI bleeding has declined in those younger than age 70 years to as low as 47 per 100,000 [2,5]. *Helicobacter pylori* eradication efforts and widespread use of proton pump inhibitor (PPI) therapy may account for this decline [6]. The incidence in older populations, however, remains stable possibly from more frequent use of aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) [4,7]. The majority of upper GI bleeding are nonvariceal (80% to 90%), of which 28% to 59% are attributable to peptic ulcer bleeding [3,4]. Patients with lower GI bleeding are half as likely to present with hemodynamic compromise or require blood transfusion and have significantly higher hemoglobin concentrations at presentation compared to patients with upper GI bleeding [8]. The mortality rate from upper GI bleeding has remained largely stable at 5% to 12%, whereas mortality rate for lower intestinal bleeding remains below 5% [4,8]. Newer surgical, endoscopic, and medical therapies in conjunction with improved ICU care have improved survival [9], and this trend will likely continue in the coming years.

INITIAL EVALUATION AND
Resuscitation the actively bleeding patient takes priority over localizing the bleeding source. The immediate goals are to replete intravascular volume and prevent irreversible shock. However, even in situations of exsanguinating hemorrhage, limited attempts to localize bleeding while resuscitation continues may be required to help direct a surgical or angiographic approach.

An initial brief history and physical examination that includes serial measurement of vital signs and evaluation of the volume and character of bleeding helps determine the urgency and degree of resuscitation necessary. Tachycardia (pulse > 100 beat per minute), hypotension (systolic blood pressure < 100 mm Hg), or orthostatic hypotension (an increase in the pulse of ≥20 beats per minute or a drop in systolic blood pressure of ≥20 mm Hg on standing) indicates significant intravascular volume depletion [4]. Insight into volume status can also be gained from evaluation of mucous membranes and neck veins and measurement of urine output [4]. Bleeding patients need large-bore intravenous (IV)-access catheters (e.g., peripheral catheters 16 or 18 gauge or central venous access), supplemental oxygen, correction of coagulopathies, and prompt packed red blood cell transfusion to patients with tachycardia, hypotension, or hemoglobin less than 7 g per dL in most settings.

Older patients with hemodynamic compromise or shock have a higher risk of mortality; therefore, they need urgent resuscitation and close monitoring. In situations of massive hematemesis, endotracheal intubation provides airway protection and facilitates endoscopic evaluation and therapy. Chest pain may imply a superimposed myocardial infarction or dissecting aneurysm, whereas a history of abdominal vascular surgery adds aortoenteric fistula to the differential diagnoses. GI bleeding is generally not associated with significant abdominal pain, and its presence could signify hemobilia, intestinal infarction, or intestinal perforation.

Although initial aggressive resuscitation is crucial, care must be taken to avoid over-resuscitation. Recent evidence and guidelines support a more restrictive approach to transfusion, with a hemoglobin target of 7 g per dL in most cases [10,11]. Restrictive transfusion goals have been associated with improved outcomes and lower mortality, particularly for patients with cirrhosis and portal hypertension, wherein aggressive resuscitation can increase portal pressure and lead to recurrence of bleeding [10]. However, appropriate target hemoglobin for transfusion depends on the clinical context, with higher goals reasonable in patients with active cardiac ischemia or massive bleeding.

Correction of coagulopathy, when possible, is another important
consideration in the initial management of acute GI bleeding. Risk of GI bleeding appears to be similar in patients taking novel anticoagulants such as dabigatran or rivaroxaban, when compared with patients on warfarin [12]. Fresh frozen plasma or prothrombin complex can be administered to rapidly reverse the effect of warfarin. Although the lack of available reversal agents for the newer anticoagulants has been problematic, this concern may soon be alleviated with the development of effective reversal agents [13].
FURTHER EVALUATION AND MANAGEMENT

Resuscitation may need to be continued even after the initial volume deficit has been corrected if there is evidence of ongoing or renewed bleeding. Because of the laxative properties of fresh blood in the GI tract, repeated passage of liquid blood per rectum implies ongoing or recurrent bleeding. As bleeding stops, the stool becomes formed and converts from red or maroon blood to darker stool and eventually to brown stool that contains occult blood, which may persist for as long as 2 weeks after GI bleeding has ceased.

In patients without hematemesis, a nasogastric (NG) tube aspirate of red blood may be a poor prognostic sign [3,4], but the lack of red blood or coffee ground material does not exclude an upper GI bleeding source [4]. NG lavage does not appear to affect clinical outcomes, although it may help predict the presence of high-risk lesions [14]. Clinical variables at presentation in combination with endoscopic findings have been used to triage and risk-stratify patients, assess risk of poor outcomes, and aid in guiding management [3,4]. Clinical variables at presentation in combination with endoscopic findings have been used to triage and risk-stratify patients, assess risk of poor outcomes, and aid in guiding management [3,4]. Clinical variables at presentation in combination with endoscopic findings have been used to triage and risk-stratify patients, assess risk of poor outcomes, and aid in guiding management [3,4]. Clinical variables at presentation in combination with endoscopic findings have been used to triage and risk-stratify patients, assess risk of poor outcomes, and aid in guiding management [3,4]. Clinical variables at presentation in combination with endoscopic findings have been used to triage and risk-stratify patients, assess risk of poor outcomes, and aid in guiding management [3,4]. Clinical variables at presentation in combination with endoscopic findings have been used to triage and risk-stratify patients, assess risk of poor outcomes, and aid in guiding management [3,4].

The Glasgow–Blatchford score is a validated tool based solely on pre-endoscopic clinical variables scored from 0 to 23 (Table 203.1), with higher values predictive of higher risk. Patients with scores of 0 are at low risk of rebleeding and mortality and can be considered for outpatient management [4,15,16]. The Rockall score can be calculated prior to and after endoscopy (Table 203.2), with higher scores predictive of higher risk of a poor outcome [16,17]. The Glasgow–Blatchford score may be superior to pre-endoscopic Rockall score in predicting need for endoscopic intervention, whereas the full (postendoscopic) Rockall is superior in predicting risk of death [18]. A newer simple pre-endoscopic risk score, AIMS65, includes five clinical measures (albumin < 3 g per dL, international normalized ratio > 1.5, mental status change, systolic blood pressure < 90 mm Hg, and age > 65 years) [19]. Recent evidence suggests that this score performs as well or better than the Glasgow–Blatchford score in predicting mortality, length of stay in hospital, and rebleeding [20]. Although their exact role in clinical management continues to be evaluated, these scores will likely continue to have an increasing role in patient care, particularly in triage of patients at the time of presentation to ICU, inpatient, or outpatient settings [16].

DIAGNOSTIC EVALUATION

Bedside Diagnosis

Although hematemesis is clearly a symptom of upper GI bleeding, black tarry melenic stool predicts an upper GI bleeding source, and brighter colors of red in the stool are more often associated with a distal colonic bleeding source. However, color of bloody stool may not always be helpful in predicting the level of GI bleeding and is subject to interpretation variability by both patients and physicians. Stool color identified by the patient on a color card may be more reliable than physician history in suggesting the level of bleeding in the GI tract [21]. When bright blood in the stool (implying a lower GI bleed) is associated with hemodynamic compromise, as many as 11% of patients may have an upper GI bleeding source, even if the NG aspirate is negative [3,4]. In this setting, an upper endoscopy may be the first endoscopic evaluation even though the presenting symptom is hematochezia.

Upper Endoscopy

When bleeding is suspected to originate proximal to the jejunum, esophagogastroduodenoscopy (EGD; upper endoscopy) is the diagnostic procedure of choice. This identifies the bleeding source in 80% to 90% of cases with a high degree of accuracy, provides therapeutic options, and carries low morbidity [3,4]. Endoscopy has the added advantage of detecting prognostic signs (Table 203.2) and classifies bleeding stigmata as high or low risk for rebleeding based on the Forrest grade (Table 203.3).

<sup>a</sup> Includes Forrest grades IA and IB.
Forrest grade IA indicates spurting or arterial bleeding and IB indicates oozing bleeding.

Even when an exact diagnosis cannot be made, localizing the bleeding to a specific region within the upper GI tract can be helpful to the surgeon (if resection is indicated) or interventional radiologist (if embolization of the bleeding vessel is recommended). Erythromycin or metoclopramide can be administered IV to induce gastric emptying and clear the stomach of blood and clots prior to endoscopy [22]; repeated lavage with saline through a wide-bore orogastric tube may also be used for this purpose. However, routine gastric lavage may not be necessary. Complications related to endoscopy are higher when the procedure is performed on an emergency basis.

The timing of endoscopy for upper GI bleeding continues to be evaluated. Endoscopy within 12 hours of presentation increased the use of endoscopic therapy but did not reduce rebleeding rates or improve survival rates [23]. However, endoscopy within 24 hours did demonstrate a reduction in the length of hospital stay and need for surgical intervention [24]. Patients with bloody NG aspirate did benefit from endoscopy within 12 hours to reduce the blood transfusion requirements and length of hospital stay [23]. Reduction of the window for endoscopy to 6 hours did not demonstrate benefit in mortality, need for surgery, or transfusion requirements [25]. Current guidelines recommend urgent endoscopy (within 24 hours) for patients with malignancy or cirrhosis, hematemesis, signs of hypovolemia, or hemoglobin less than 8 g per dL [26].

The benefit of a repeat “second-look” endoscopy is an area of investigation, especially in the presence of factors associated with an increased risk of rebleeding (history of peptic ulcer disease, previous ulcer bleeding, presence of shock at presentation, ulcers >2 cm, large underlying bleeding vessel ≥2 mm diameter, and ulcers located in lesser curve of stomach or posterior/superior duodenal bulb) [27,28]. A meta-analysis concluded that second-look endoscopy was associated with a decreased risk of recurrent bleeding but did not alter subsequent surgery rates or mortality [29]. A recent decision-effectiveness and cost-effectiveness analysis suggested that routine second-look endoscopy is not warranted, but for cases with a rebleeding risk of 31% or higher, cost–benefit analysis of second look is favorable [30]. Scheduled repeat endoscopy therefore is not routinely recommended, but can be considered on an individual case basis if clinical signs of recurrent bleeding are present or if there are questions about adequate hemostasis [26,31].

Enteroscopy
If a small bowel lesion is suspected after a negative upper endoscopy, a longer endoscope can be used to evaluate the proximal small bowel (push enteroscopy), which allows visual inspection and endoscopic hemostasis of bleeding lesions as far distal as the proximal jejunum [32]. Bleeding lesions beyond the reach of a push enteroscope can potentially be approached using single- and double-balloon enteroscopy, techniques that allow for visualization of most of the small bowel. Balloons at the endoscope tip and an overtube can be consecutively inflated and deflated while inserting and pulling out the endoscope to allow the bowel to pleat over the overtube, thus allowing deep endoscope insertion into the small bowel, either through the mouth or the anus [32]. Diagnostic yield for push enteroscopy in evaluation of obscure bleeding is 24% to 56%, compared with 43% to 81% for balloon-assisted enteroscopy [33]. Single- and double-balloon enteroscopy also have utility in determining the source of obscure GI bleeding in patients with surgically altered anatomy such as Roux-en-Y gastric bypass [34].

**Sigmoidoscopy/Colonoscopy**

When a distal lower GI bleeding source is suspected, early sigmoidoscopy may be helpful if the bleeding is not of a magnitude that would prevent adequate visualization. For most situations, however, colonoscopy replaces sigmoidoscopy as the diagnostic approach. Early colonoscopy provides a higher yield of the bleeding source compared to radiologic studies, especially when performed within 24 hours of presentation [35]. In patients with severe hematochezia and diverticulosis, urgent colonoscopy (within 6 to 12 hours of hospitalization or diagnosis of hematochezia) after rapid bowel purge can provide endoscopic treatment of diverticular hemorrhage and may prevent recurrent bleeding and decrease the need for surgery [36]. Only 20% of patients with lower GI bleeding, however, have a lesion amenable to endoscopic intervention [37]. In a community practice setting, a recent retrospective database analysis found that less than 5% of patients received endoscopic hemostasis [38]. Even when the exact cause of bleeding cannot be determined, colonoscopy may localize fresh blood to a segment of colon and direct further therapies such as angiotherapy or surgery. Patients with subacute bleeding or hemorrhage that has ceased can undergo adequate bowel preparation followed by semiurgent colonoscopy.

**Video Capsule Endoscopy**

Video capsule endoscopy (VCE) has emerged as a useful tool for evaluation of obscure GI bleeding, detecting culprit lesions with rates of 35% to 77% [39]. Diagnostic yield and effect on patient management are improved with early deployment (within 3 days of admission) [40]. VCE
is useful for localizing small bowel bleeding sites to guide management with deep enteroscopy or other approaches [33]. Capsule endoscopy has most often been used after both upper and lower endoscopies have been performed. Recent studies have examined the use of VCE earlier in the diagnostic algorithm, either as the initial step in evaluation [41] or immediately following negative EGD [42] in patients with acute GI bleeding, with encouraging results. Larger, randomized studies are needed to clarify the optimal use of VCE in acute bleeding.

Radionuclide Bleeding Scan

The technetium-99m-labeled red blood cell scan (scintigraphy) performed at the bedside offers a noninvasive diagnostic approach to patients suspected of having GI bleeding originating beyond the reach of an endoscope, especially in unstable patients where bowel preparation or endoscopy cannot be safely performed. Although bleeding rates as low as 0.1 mL per minute can be detected by this method, the patient should have evidence of ongoing bleeding during the study [8]. Scintigraphy may help to identify patients needing interventional treatment from those who can be managed conservatively [43]. Combination with CT imaging provides higher precision in localizing bleeding site as well as additional anatomic information that may be useful for management [43]. If the test localizes bleeding, angiography or endoscopy (push enteroscopy, colonoscopy, double-balloon enteroscopy, capsule endoscopy) is needed to confirm the site, to further define the cause, and to offer therapy for ongoing bleeding [8]. If the test is negative, colonoscopy followed by capsule endoscopy is usually performed to evaluate potential small bowel and colonic bleeding sources [32].

Mesenteric Arteriography

Because a more rapid bleeding rate is necessary for a positive arteriogram (0.5 mL per minute), this procedure is typically performed after active bleeding is documented on a radionuclide bleeding scan [8,43]. However, because of the intermittent nature of bleeding and the variable timing of mesenteric arteriography, a positive red blood cell scan does not always result in a diagnostic arteriogram [8]. Arteriography is also useful for upper GI bleeding sources not visualized on upper endoscopy because of rapid bleeding or a blood-filled stomach.
THERAPEUTIC PROCEDURES FOR HEMOSTASIS

Evidence-based recommendations for the therapy of GI bleeding are summarized in Table 203.4.

**TABLE 203.4 Summary of Evidence-based Findings for Therapy of GI Bleeding**

- Octreotide infusion is an effective adjunct to endoscopic therapy for variceal bleeding [66,71].
- Endoscopic variceal band ligation is the therapy of choice for esophageal variceal bleeding [79].
- TIPS and BRTO are effective nonendoscopic modalities of treating variceal hemorrhage [88,91].
- Identification of patients at high risk for rebleeding and mortality, and early diagnostic endoscopy with hemostatic therapy in patients with high-risk stigmata of rebleeding improve outcome in acute nonvariceal upper GI bleeding [16,19,26,52].
- Intravenous proton pump inhibitors, administered either as intermittent bolus doses or continuous infusion, decrease risk of rebleeding, need for surgery, and death in peptic ulcer bleeding [108–110,112].
- Early colonoscopy for acute lower GI bleeding may identify a bleeding source more often compared to radiologic studies, but the choice of diagnostic test may not affect patient outcomes [35].

---

GI, gastrointestinal; TIPS, transjugular intrahepatic portosystemic shunt; BRTO, balloon-occluded transvenous obliteration.

**Endoscopic Therapy (Endotherapy)**

Endotherapy offers a convenient and expedient method for treatment of GI bleeding. Although endotherapy was primarily used for the treatment of upper GI and peptic ulcer bleeding, these modalities can also be applied to patients with lower GI bleeding [4,44,45]. Endotherapy is indicated for all patients with high-risk lesions because of the significant
risk of persistent or recurrent bleeding (22% to 55%) and even death if left untreated [3,4,46]. Randomized trials have demonstrated that endotherapy for upper GI bleeding decreases further bleeding, shortens hospital stay, decreases transfusions, decreases emergency surgery, decreases mortality, and lowers costs [47]. Optimal therapy for adherent clots remains controversial; a meta-analysis demonstrated reduced rebleeding rates (RR 0.35, 95% confidence interval [CI] 0.14 to 0.82) with endoscopic removal of clot and treating of the uncovered lesion, but no change in length of hospitalization, need for surgery, transfusion requirements, and mortality compared to only medical therapy [48–50]. However, vigorous lavage of adherent clot can uncover stigmata requiring endoscopic treatment in nearly half of patients and can be performed at the discretion of the endoscopist [11].

The most common modalities of endoscopic therapy used are thermal therapy (heater probe, bipolar probe, argon plasma coagulation), injection therapy (epinephrine, hypertonic saline, sclerosing solutions), and mechanical therapy (hemoclips, endoloops, and band ligation). Newer endoscopic techniques, including over-the-scope clips, endoscopic suturing, mucosal ablation devices, fibrin glue injection, hemostatic spray, and endoscopic ultrasound-guided angiotherapy, may improve success rates in treatment of high-risk lesions [51]. The treatment modalities are generally comparable with respect to efficacy and safety even when used in combination [3]. In a Cochrane database systemic review, addition of an alternative modality of endotherapy to epinephrine injection alone reduced further bleeding (odds ratio [OR] 0.53), need for emergency surgery (OR 0.68), and mortality (OR 0.50) in high-risk ulcers, although no particular form of treatment appeared to be superior to others [52]. These findings are similar to prior meta-analysis and mirror published guidelines [26,53]. However, despite successful endotherapy, rebleeding can occur in up to 30% of patients. The Baylor bleeding score, using patient age, number of illnesses, illness severity, site of bleeding, and stigmata of bleeding, has been proposed to predict the likelihood of rebleeding [54] and may be useful in determining which patients may benefit from second-look endoscopy [30].

**Angiotherapy**

Intra-arterial vasopressin and/or embolization are used for angiographic control of various bleeding lesions [8,55]. A recent randomized study comparing urgent colonoscopy to radionuclide scanning followed by angiography demonstrated no differences in hospital stay and transfusion requirements despite the fact that colonoscopy identified a definitive bleeding source more often. However, this study used only vasopressin infusion and did not use embolization as a mode of angiotherapy [56].
Vasopressin has potential to cause cardiovascular complications. Gelfoam and metal coils used for embolic therapy after superselective cannulation of the bleeding artery are effective because they can be delivered close to the terminal bleeding vessel and result in localized thrombosis with vessel occlusion. Embolization successfully controls bleeding in 52% to 94% of patients, with approximately 10% of these patients requiring repeat embolization for recurrent bleeding [57]. There is a risk of bowel ischemia following embolization, but this is usually minor and self-limited [55].

Angiotherapy may be a first-line treatment for uncontrolled lower GI bleeding from lesions such as diverticula and angiodysplasia, but its use in the upper gut is reserved for peptic ulcer bleeding that is not localized or controlled by endotherapy. Angiotherapy can be comparable to surgical intervention when endoscopic therapy fails for bleeding peptic ulcers. A retrospective analysis demonstrated no difference between embolization and surgery in recurrent bleeding (29.0% and 23.1%), additional surgery required (16.1% and 30.8%), and mortality (25.8% and 20.5%) despite an older population and higher prevalence of heart disease within embolization group [58]. The timing for the use of angiography and angiotherapy must be individualized and usually is a consensus decision by the involved physicians.

Surgical Therapy

The appropriate timing of when a surgeon should be involved in the care of a bleeding patient is physician and institution dependent, and ranges from an early team approach at presentation to involvement once the risk of significant morbidity and mortality are established after a poor response to medical and endoscopic therapy. Surgical intervention is an effective and safe alternative for patients with uncontrollable bleeding or those unable to tolerate additional bleeding [59]. Prior to surgical intervention, a repeat endoscopy for a patient with persistent or recurrent bleeding can be considered owing to lower risks of side effects from endoscopy compared to surgery [60,61]. A possible exception may be ulcers >2 cm in hypotensive patients where the risk of rebleeding is extremely high with repeat endoscopic therapy [26,61]. Patients with massive hemorrhage that overwhelms the resuscitation effort may need to proceed directly to the surgical suite during ongoing resuscitation. If these patients are high-risk surgical candidates, angiotherapy or a percutaneously or surgically placed portal-hepatic shunt for variceal
bleeding may be alternatives.
SPECIFIC BLEEDING LESIONS

Variceal Upper Gastrointestinal Bleeding

Portal hypertension, most frequently a consequence of cirrhosis, leads to portosystemic collateral circulations at the squamocolumnar junctions in the gut (i.e., gastroesophageal, anal, and peristomal), which progressively enlarge to form varices. Bleeding from gastroesophageal varices characteristically is brisk and typically presents as hematemesis, melena, or hematochezia in association with hemodynamic instability. The presentation may be less dramatic because acute blood loss can be self-limited in 50% to 60% of cases [62]. One-half to two-thirds of patients with cirrhosis and acute upper GI bleeding have nonvariceal sources of hemorrhage documented by endoscopy [63]. Upper GI variceal bleeding occurs in at least 20% of all patients with cirrhosis who develop varices, with bleeding episodes carrying a mortality rate of at least 20% at 6 weeks [64,65]. Once active bleeding stops, the likelihood of recurrent variceal hemorrhage is 40% within 72 hours and 60% within 10 days if no definitive treatment is pursued [48]. Risk factors associated with variceal rupture include a portal pressure gradient greater than 12 mm Hg, large variceal size (greater than 5 mm), and progressive hepatic dysfunction [66]. Endoscopic findings that implicate esophageal or gastric varices as the bleeding source include the red sign, where one varix is brighter red than the others from microtelangiectasias (red-sign variants include red-wale marks, cherry-red spots, hematocystic spots, and diffuse redness of varix), and the white-nipple sign, in which a fresh fibrin clot may be seen protruding from a varix [66,67]. Endotracheal intubation protects the airway from aspiration of blood in obtunded patients, especially in the setting of massive bleeding [68]. Additional complications that must be addressed include alcohol withdrawal, aspiration, infection, and electrolyte imbalances.

Octreotide is a somatostatin analog that decreases splanchnic blood flow and portal pressure, controlling variceal bleeding in as many as 85% of patients [69,70] with an efficacy approaching that of endoscopic therapy and providing improved visibility during subsequent endoscopy [70–72]. Octreotide is typically administered IV as a bolus dose of 50 to 100 μg followed by continuous infusion of 25 to 50 μg per hour continued 3 to 5 days after diagnosis, but tachyphylaxis may limit efficacy of repeated bolus administrations [66,71–75]. Aside from transient nausea and abdominal pain with bolus doses, significant adverse effects from octreotide are rare. Vasopressin, once widely used in this setting, has a significant cardiovascular side effect profile and for this reason has been
replaced by octreotide.

Infection (specifically spontaneous bacterial peritonitis) occurs in patients with cirrhosis and GI bleeding of any type in 25% to 50% of cases, leading to increased bleeding and mortality [76]. Antibiotic prophylaxis with a fluoroquinolone (norfloxacin or ciprofloxacin) in all cirrhotics with GI hemorrhage reduces the rate of bacterial infections and improves survival [77,78]. IV ceftriaxone is an alternative for patients with advanced cirrhosis or when quinolone-resistant organisms are suspected [78].

Endoscopic evaluation should be performed urgently (within 12 hours) in patients in whom variceal bleeding is suspected [79]. Endoscopic band ligation has gained acceptance as the preferred endoscopic treatment for patients with bleeding esophageal varices, with rapid obliteration of varices, and low rates of complications and rebleeding (Table 203.4) [66,80]. Endoscopic variceal sclerotherapy (injecting a sclerosing solution into the variceal lumen or into the adjacent submucosa), although successful in controlling variceal bleeding, is associated with a 20% to 40% incidence of complications, and has largely been relegated to a second-line therapeutic modality, reserved for patients in whom band ligation is technically difficult [66,81]. Complications of band ligation include recurrent bleeding from treatment-induced esophageal ulcers, stricture formation, esophageal perforation, and acceleration of portal hypertensive gastropathy [82]. Repeat variceal band ligation is performed until varices are obliterated because this approach reduces the incidence of rebleeding [66]. Appropriate interval for repeat band ligation is controversial, with recommendations ranging from 1 to 8 weeks [79].

Gastric varices are detected in approximately 20% of patients with portal hypertension, but can also occur from splenic vein thrombosis. Gastric varices bleed less often, but blood loss can be more substantial compared to esophageal varices [83]. When available, endoscopic injection of a tissue adhesive such as butyl cyanoacrylate is effective, with hemostasis rates approaching that of transjugular intrahepatic portosystemic shunt (TIPS) with fewer recurrences [66,84]. Complications include a propensity for embolic phenomenon posttreatment, including massive pulmonary embolism [85]. Gastric variceal hemorrhage dictates earlier consideration of nonendoscopic therapeutic approaches such as TIPS placement. Embolization of the short gastric veins and varices is a potential management option for isolated gastric varices. In the setting of splenic vein thrombosis, splenectomy may be an appropriate therapy.

A TIPS (an iatrogenic fistula between the hepatic vein and portal vein) decreases portal pressure gradient to less than the 10 mm Hg necessary for the formation of esophagogastric varices [86]. TIPS is commonly recommended if esophageal variceal bleeding recurs after two or more
endoscopic attempts at therapy [87], if active bleeding is not responsive to variceal ligation or sclerotherapy, or as first-line treatment for gastric variceal bleeding [66]. Complications include transient deterioration of liver function, new or worsened hepatic encephalopathy (25%), and shunt insufficiency from thrombosis or stenosis [86]. When placed in an emergency setting to control active bleeding, a 10% in-hospital mortality and 40% 30-day mortality have been reported [86,88,89].

Balloon-occluded retrograde transvenous obliteration (BRTO) is an endovascular approach used for managing gastric varices. This technique requires a natural gastrorenal or gastrophrenic shunt, which occur in 95% of cases of gastric varices [90]. A balloon catheter is used to occlude the shunt, following which a sclerosant, for example, ethanolamine is injected into the varix [90]. A recent meta-analysis found a pooled clinical success rate of 97% with a major complication rate of 2.6% [91]. Complications of BRTO include venous thrombosis and pulmonary embolism, renal failure, and infection [90,91]. A significant concern is recurrence or exacerbation of esophageal varices after BRTO because of flow and pressure redistribution [91].

Surgically created shunts reliably control acute bleeding (>90%) and prevent rebleeding (<10%) [92,93] but are limited by high operative mortality and postprocedure encephalopathy. Therefore, surgical shunts are only considered in well-compensated cirrhotic patients with good long-term prognoses [93].

Esophageal or gastric balloon devices may be used for direct tamponade of the bleeding source when definitive therapy is not immediately available. There are two basic types of balloon tubes: those with gastric and esophageal balloons (Sengstaken–Blakemore and Minnesota tubes) and those with a large gastric balloon alone (Linton–Nachlas). The incidence of rebleeding is expectedly high. Other complications (aspiration, balloon migration, airway occlusion, perforation, pressure necrosis) occur in 15% to 30% of patients, including death in 6% [94]. Instructions for correctly placing and maintaining a specific balloon device are included as a product insert and should be reviewed before balloon use.

Peptic Ulcer Bleeding

The most important etiologic factors for peptic ulcer disease are *H. pylori* infection and NSAID use. Although the role of *H. pylori* infection in ulcer formation is established, its exact role in precipitating ulcer bleeding is
controversial [95]. With long-term NSAID use, there is a greater risk of
gastric ulceration compared to duodenal ulceration. Bleeding risk varies
depending on NSAID dose and the agent used. Other cofactors, including
older age, a history of past peptic ulcers (especially with ulcer bleeding),
and a history of coronary disease, may be independent risk factors for
ulcer bleeding [96,97]. Population-based studies have suggested that
ulcer formation and bleeding occur even with cyclooxygenase 2 (COX-2)
inhibitors, albeit at a lower rate [98]. Both COX-2 inhibitors and their
nonselective analogs are associated with increased risk of ulcer bleeding
when taken in conjunction with anticoagulants such as warfarin [99].
This risk with nonselective NSAIDs and anticoagulation taken together
may be as high as 13 times that of patients taking neither NSAIDs nor
anticoagulants [100]. Less than 1% of peptic ulcers result from
hypersecretory states such as Zollinger–Ellison syndrome. In a
proportion of patients, the disorder remains idiopathic, because of either
an inability to demonstrate *H. pylori* or lack of a history of obvious
NSAID use.

Although 80% or more patients with acute GI bleeding eventually stop
bleeding spontaneously [101], it is important to recognize factors
associated with higher risk for morbidity and mortality, including older
age, large ulcer size (more than 2 cm), large-volume bleeding, and onset
of bleeding while hospitalized. A recent meta-analysis demonstrated a
clear relationship between presence of comorbid conditions and risk of
death from peptic ulcer bleed [102]. Other prognostic information can be
obtained from endoscopy findings, which should detail whether stigmata
of recent bleeding (active bleeding, nonbleeding visible vessel, adherent
clot, flat pigment spots) or no stigmata (clean ulcer base) were found in
association with the ulcer (Table 203.3). These criteria can be used to
predict rebleeding and the need for therapeutic intervention [46,101,103].
Patient age, hemodynamic parameters, comorbidities, and endoscopic
findings have been compiled into scoring system by Rockall et al. [104]
and Blatchford [4]. The Rockall score (Table 203.2) has been validated as
a predictor of short-term mortality, but not recurrent bleeding [17].

In vitro data suggest that gastric acid plays an important role in
impairing platelet aggregation, clot lysis, and increased fibrinolytic
activity that is reversible at pH values above 6 to 6.5 [105,106]. PPIs can
effectively raise gastric pH >4.0, but their ability to elevate pH to >6.0 is
unclear [105]. However, these differences in gastric pH may not translate
into clinical benefit. In contrast to histamine-2 receptor antagonists, PPIs
have been established as beneficial in acute nonvariceal upper GI
bleeding, with a rapid increase in gastric pH, especially with IV PPI, when
a mean pH of 6 is reached approximately 1 hour sooner than oral PPI
[107]. A Cochrane meta-analysis reaffirmed the established
understanding that IV PPI therapy in the setting of peptic ulcer disease
decreased rebleeding rates (OR 0.40, 95% CI 0.24 to 0.67), need for urgent surgery (OR 0.50, 95% CI 0.33 to 0.76), and risk of death (OR 0.53, 95% CI 0.31 to 0.91) [108]. IV PPI therapy upon presentation (when compared to IV PPI therapy initiated after endoscopic therapy) decreases the need for endoscopic therapy but not rebleeding rates, blood transfusion requirements, or mortality, a result supported by meta-analysis [109,110]. This approach has been demonstrated to be cost effective, reducing the need for endoscopic therapy by 7.4% [111]. A recent meta-analysis demonstrates no difference in efficacy between IV PPI therapy when delivered as intermittent bolus dosing compared with continuous infusion in patients with endoscopically treated high-risk bleeding ulcers [112].

Mallory–Weiss Tear

A Mallory–Weiss tear represents bleeding from a mucosal disruption at the area of the esophagogastric junction and is found in approximately 5% to 15% of cases of upper GI bleeding. The classic history is a patient with vomiting of nonbloody gastric contents followed by hematemesis, although this presentation is variable (29% to 86%) [113]. Blood with the initial emesis does not exclude the diagnosis. The great majority of patients (80% to 90%) bleeding from a Mallory–Weiss tear stop bleeding without therapeutic intervention, and rebleeding rates are low (less than 5%). Endoscopy offers diagnosis and the option for endotherapy; rarely nonendoscopic measures such as angiography and embolic therapy are required.

Angiodysplasia

Angiodysplasia lesions are small (3 to 15 mm) vascular mucosal abnormalities that can cause GI bleeding from the stomach, small bowel, or colon. Bleeding upper GI lesions frequently occur in patients with chronic renal failure [114,115], whereas vascular heart disease is associated with colonic lesions [116]. The character of the bleeding usually is subacute rather than massive. Angiodysplasia typically is diagnosed at endoscopy; bleeding colonic angiodysplasia lesions can also be detected with angiography. Angiodysplasia lesions are the most frequent finding in the small bowel on wireless capsule endoscopy performed for evaluation of obscure GI bleeding. Endoscopic thermal therapy typically is successful in obliterating the lesions [117]. When large lesions are encountered, the periphery is cauterized first to obliterate the feeder vessels, and the center of the lesion is treated last [118]. Angiotherapy and surgery can be used to treat bleeding vascular lesions.
An iatrogenic risk factor for the development of GI angiodysplasia is implantation of a left ventricular assist device (LVAD), an increasingly common intervention for congestive heart failure. The prevalence of GI bleeding in patients with LVADs is 23% according to a recent meta-analysis, with the most common cause being angiodysplasia in the upper GI tract [119]. Formation of angiodysplasia is thought to be promoted by high shear forces in continuous flow LVADs, decreased activity of von Willebrand factor multimers, gut hypoperfusion caused by low pulse pressure, and changes in vascular smooth muscle tone [119]. Long-term use of anticoagulation in this population also leads to increased rates of bleeding. Endoscopic evaluation has been shown to be safe and effective in this population, detecting a bleeding source in 70% of patients [120].

Dieulafoy Lesion

Dieulafoy lesion, an unusual cause of massive bleeding, represents a mucosal defect, not an ulcer, that exposes an end artery of the same caliber as its feeding submucosal artery [121]. The lesions are typically located in the gastric cardia/proximal stomach but are rarely found in the duodenum and other parts of the GI tract including the colon and rectum [122]. Bleeding is often massive and recurrent yet difficult to diagnose. The site is minute, innocent looking, and frequently not appreciated at endoscopy once bleeding has stopped. Upper endoscopy can offer diagnosis and treat a lesion that was previously considered amenable only to surgical resection [123]. Endoscopic band ligation is one method that has been successful for hemostasis [124].

Colonic Diverticular Bleeding

Bleeding colonic diverticula are the most frequent cause of lower GI bleeding, but a definitive diagnosis (e.g., finding stigmata of recent bleeding) is established in only 20% of patients with hematochezia and colonic diverticula [125]. Diverticular bleeding demonstrated by angiography usually is localized to the right colon, whereas the left colon is the more common location when colonoscopy is performed as the diagnostic study (descending colon, 21%; rectosigmoid, 35%) [126]. The character of diverticular bleeding invariably is bright red or maroon blood per rectum, sometimes associated with orthostasis or hypotension. The majority of patients stop bleeding spontaneously, but approximately 20% to 30% rebleed.

Urgent colonoscopy after a rapid colonic purge (more than 4 to 6
hours) is recommended as an option in patients with ongoing bleeding, once the patient is resuscitated and hemodynamically stable [45]. However, a recent randomized controlled study failed to demonstrate an outcome benefit between urgent colonoscopy and radiologic studies for localization of bleeding, despite a higher likelihood of finding the bleeding source in the urgent colonoscopy group [56]. When a bleeding diverticulum is identified by the finding of a visible vessel or a pigmented protuberance [126], epinephrine injection, thermal contact therapy, or hemoclip application can be considered [44,45,127]. One study demonstrated that visualized diverticular bleeding treated with endoscopic therapy had no recurrent bleeding during a 30-month follow-up compared to 53% of patients with medical therapy alone [45]. Surgical intervention, either segmental or subtotal colectomy, is required in 18% to 25% of patients requiring blood transfusion [128]. Angiotherapy with vasopressin infusion or embolization after superselective cannulation of the bleeding vessel is an alternative approach in patients unstable for surgery.

There is limited evidence that endoscopic therapy can prevent recurrent bleeding and the need for surgery [45]. Alternatively, in patients who have stopped bleeding, elective colonoscopy can be performed during the same hospital stay, after adequate bowel preparation.

Aortoenteric Fistula

The key to recognizing an aortoenteric fistula is inclusion within the differential diagnosis of every patient with bleeding and a history of aortic graft surgery. Although fistulas can occur rarely between a native aortic aneurysm and the intestinal lumen, they more commonly occur in patients who have undergone abdominal aortic graft surgery (0.5% to 2.4%) [129]. This communication with resultant bleeding presents, on average, 4 years after the surgery. The point of intestinal breach can be anywhere from the esophagus to the colon, but occurs most often in the third part of the duodenum (75%). A massive bleeding episode may be preceded by a small “herald bleed” that stops spontaneously. The interval between the first event and the exsanguinating hemorrhage can be hours, weeks, or months (average, 1 to 3 weeks). Making the diagnosis is difficult, but upper endoscopy is useful in excluding the diagnosis by identifying another lesion that is actively bleeding or has stigmata of recent bleeding. Endoscopic visualization of the graft eroding through the intestinal wall is diagnostic but uncommon. In some cases, computed tomography of the abdomen can identify graft abnormalities such as air–fluid levels that may indicate an enteric communication [130]. Angiography has not usually been helpful in the diagnosis unless bleeding
is ongoing. If available, a vascular surgeon and an interventional radiologist should be part of the evaluating team. Graft repair surgery or an endovascular approach may be required for a confirmed diagnosis, and exploratory surgery is likely necessary for a presumed diagnosis of a fistulized or infected graft site.
REFERENCES

Stress-ulcer disease (SRMD) is a term that refers to the broad spectrum of pathologic changes in the gastric mucosa of critically ill patients as a result of physiologic stress [1]. The development of erosive disease in the setting of physiologic stress is not a new concept. In fact, descriptions of acute ulcerations of the intestines in the setting of acute burns date back more than 150 years [2]. Gastric mucosal erosions have been found at protocol endoscopy within hours of intensive care unit (ICU) admission. As many as 90% of ICU patients can have evidence of mucosal erosive disease after 3 days in the ICU [3–7]. Stress-related changes have been related temporally to a number of acute disorders including burns [5,8], cerebral lesions, stroke [6], surgical procedures [3,9,10], and other acute medical illnesses found in an ICU [4]. Fortunately, only a small proportion of these patients will have clinically evident bleeding. Management has largely focused on prevention of erosive disease through acid suppression, although this has been the subject of recent controversy because the risks of the medicines themselves must be balanced with their beneficial effects.

CLINICAL CHARACTERISTICS AND PRESENTATION

Despite the high prevalence of mucosal changes in critically ill patients, only a few will manifest clinically evident bleeding. Gastrointestinal (GI) bleeding from stress ulcers can be classified into the following: (a) occult bleeding, where blood is only detected by hemoccult testing and not by visual inspection of gastric content or stool; (b) overt bleeding, where gross or altered blood is visually evident in gastric aspirate, emesis, or
stool; and (c) clinically significant bleeding, for which blood loss is complicated by hypotension, tachycardia, orthostasis, or drop in hemoglobin more than 2 g per dL [11]. Using these definitions, occult bleeding can occur in 15% to 50% of ICU patients, overt bleeding in approximately 5%, and clinically significant bleeding occurs in 1% to 4% of critically ill patients [1,11,12].

The incidence of bleeding from stress ulcers appears to be decreasing over the past several decades. A pooled analysis of studies performed between 1980 and 1998 revealed an incidence of 17%, whereas a similar analysis done for studies published between 1993 and 2010 showed an incidence less than 1% [13]. This improvement has been largely attributed to advances in general ICU care over this time period, including but not limited to routine use of prophylactic medications and earlier initiation of enteral feeding.

When bleeding does occur, it has profound implications. A study done in 2001 showed significant increases in mortality and length of ICU stays when patients with GI bleeding were compared to those who did not bleed [14]. In absolute numbers, mortality rates can be as high as 45% to 55% for patients with clinically significant bleeding [12,14]. This is significantly higher (relative risk 2.2 to 3.7) when compared to patients without bleeding. However, this relationship loses significance when controlled for comorbid medical conditions and other intercurrent factors. This suggests that bleeding is more a barometer of severity of critical illness rather than a direct contributor to death [12,14].
RISK FACTORS

Although by definition, stress ulcer disease is associated with physiologic stress, certain specific disease conditions seem to have a more profound impact on development of SRMD. In a landmark trial in 1994, Cook et al. retrospectively analyzed 2,252 patients for development of ulcer disease. Respiratory failure (need for mechanical ventilation >48 hours) and coagulopathy (platelet count <50,000/µL, international normalized ratio >1.5, or partial thromboplastin time >2 times the upper limit of normal) were significant risk factors by multivariate analysis with odds ratios (ORs) of 15.6 and 4.3, respectively \[15\]. A more recent analysis of 1,034 patients found chronic liver disease, coagulopathy, need for vasopressors, renal replacement therapy, and use of acid suppression in the first 24 hours of ICU admission to be significant predictors of clinically significant bleeding \[12\]. Additional risk factors are outlined in Table 204.1.

PATHOPHYSIOLOGY

SRMD occurs when, in the setting of critical illness, the elaborate protection mechanisms of the stomach lining are broken down. Gastric epithelial cells secrete a thick mucus layer that acts as physical barrier against stomach acid and the enzyme pepsin. In addition, bicarbonate ions diffusing across the mucosa and trapped in the mucus layer act as a chemical barrier buffering acidic gastric contents [11,13]. Finally, any injury that does occur is rapidly repaired by moving new epithelial cells through the gastric unit to the mucosal surface of injury, an energy-intensive process [1,13]. Gastric regulatory factors control these processes, of which the most important are prostaglandins [13].

In the setting of critical illness, several factors work to disrupt this intricate system (Fig. 204.1). The key inciting event for SRMD is splanchnic hypoperfusion, specifically gastric hypoperfusion, partly from systemic hypotension and selective shunting of blood away from the splanchnic circulation to essential organs like the kidneys, liver, and brain. This results in gastric mucosal hypoxia, with a decrease in prostaglandin production and an increase in nitric oxide and free oxygen radicals in the mucosa. Nitric oxide leads to vasodilation, with resultant mucosal hyperemia and reperfusion injury, whereas free oxygen radicals are directly toxic to cells. With cell death, pro-inflammatory cytokines are released, which further propagate the injury [11]. In the setting of hypoxia, the mucous bicarbonate barrier breaks down, exposing the gastric epithelium to damage from back diffusion of hydrogen ions as well as direct injury from the protease pepsin. Given the lack of oxygenated blood, the gastric unit is not able to produce the energy needed to replace these damaged epithelial cells [13]. Gastric acid plays a key role in pathogenesis despite the fact that secretion is usually normal or decreased in the setting of critical illness [3,16]. This is illustrated by a number of studies that have shown that raising the gastric pH above 3.5 to 5 can prevent mucosal injury, an effect at least partially explained by optimized mucosal healing and clot formation at higher pH levels [17]. Additional factors such as elevated gastrin and pepsin levels, increased intraluminal bile and urea concentrations, and decreased gastric motility also contribute to the pathogenesis of SRMD [11,18,19].
FIGURE 204.1 Pathophysiology of stress-related mucosal disease. In the presence of physiologic stress, hemodynamic and endocrine and paracrine mechanisms lead to decreased blood flow in the splanchnic and specifically gastric circulation. This, in turn, leads to the breakdown of the gastric mucosal defense mechanism, which allows gastric acid and pepsin to erode the gastric mucosa [1,11,13]. HCO₃⁻, bicarbonate; PGs, prostaglandins; ROS, reactive oxygen species; NO, nitric oxide.
PROPHYLAXIS

Management of SRMD has largely focused on prophylaxis. By identifying patients at risk of mucosal disease and intervening with pharmacologic therapy before damage occurs, the thought is that bleeding and further morbidity can be prevented. Despite this seemingly simple concept, and despite the fact that stress ulcer prophylaxis has been standard of care for nearly two decades, this remains an area of considerable controversy [20,21].

Some of the controversy stems from the fact that agents used for prophylaxis do not reverse the underlying pathophysiology. Instead, acid suppressive medications prevent damage to the mucosa from the physiologic acidic gastric environment in the setting of the breakdown of the protective measures. This is not without merit because the acid environment also inhibits clot formation and promotes the damaging effects of pepsin [11]. Acid suppression as a means of preventing stress-related bleeding has been proven effective in multiple studies [17] and has become standard of practice, used in ICU patients [22,23] and as part of the sepsis management guidelines [24]. Navigating these standards of practice to provide the best care for patients requires an understanding of the literature and limitations of published outcomes data.
REGIMENS FOR PROPHYLAXIS

Histamine-2 Receptor Antagonists

Histamine-2 receptor antagonists (H2RAs) are an older class of acid suppressants that exert their effects by blocking the action of histamine on the histamine-2 (H2) receptor on the basolateral membrane of parietal cells, thus reducing acid secretion. They are effective in reducing clinically significant GI bleeding in SRMD by over 50% when compared to placebo [17,25]. H2RAs are typically administered intravenously either as bolus dosing or as a continuous infusion. Although continuous infusion has a greater effect on suppressing gastric acid, whether this offers a clinical advantage over bolus dosing is unclear, and bolus dosing is likely satisfactory to achieve the desired endpoint of reducing GI bleeding [26–28].

Proton Pump Inhibitors

Proton pump inhibitors (PPIs) block the final pathway for acid secretion by irreversibly inhibiting H+/K+-ATPase in gastric parietal cells. Like H2RAs, they are often administered intravenously, usually as bolus dosing; oral therapy can be used as well. Over the past several years, PPIs have overtaken H2RAs as the most frequently used agents for stress ulcer prophylaxis [22,23,29] and have been recommended for use over H2RAs in the Surviving Sepsis guidelines [24]. This shift to PPIs over time is based on their potential superiority over H2RAs in the degree of acid suppression, durability of acid suppression, and clinical outcomes in studies evaluating peptic ulcer disease, nonsteroidal anti-inflammatory drug (NSAID)-induced erosive disease, peptic esophagitis, and gastroesophageal reflux disease [30–34].

Despite these potential advantages, data supporting the use of PPIs for stress ulcer prophylaxis are equivocal at best. The majority of available clinical trials over the past decade have compared PPIs to H2RAs, with conflicting results. Some show no difference between the two agents [35,36], others show that PPIs are superior to H2RAs [37,38], and yet others show that PPIs may be worse at preventing bleeding than H2RAs [29,39]. Trials comparing PPI to placebo have shown no significant differences in rates of bleeding [25,35].

Some of the conflicting data can be explained by the fact that the PPI era coincided with a marked decrease in incidence of SRMD-related bleeding [38]. As a result, many of these studies are plagued by low event rates and are largely underpowered to detect true differences in their
comparator groups [21]. In addition, many of these studies have methodologic issues making them subject to various forms of bias [21,36–38]. Further, gastric acid plays only a peripheral role in the pathophysiology of SRMD; hence, more acid suppression may not necessarily lead to a better outcome. In contrast, H2RAs have the additional advantage in that they may limit reperfusion injury, a phenomenon that has been observed in animal models [29]. Regardless, based on their method of action and magnitude of acid suppression, PPIs are likely effective for stress ulcer prophylaxis, but they cannot be definitively recommended over H2RAs based on currently available studies.

Sucralfate

Sucralfate is the aluminum salt of sulfated sucrose and does not affect gastric acidity. In contrast to the mechanism of action of acid suppressants, this agent lines denuded gastric mucosa and provides an additional layer of protection against acidic gastric contents. Sucralfate is usually given as a slurry prepared by dissolving 1 g of sucralfate in 5 to 15 mL of water, administered through a nasogastric tube. In terms of efficacy, available data suggest that sucralfate is better than placebo and antacids in preventing stress ulcer bleeding; however, it may be no better and potentially worse than H2RAs in this regard, although data and expert opinion vary [17,40]. Despite this, sucralfate is an agent that remains in the conversation owing to the potential benefit of reducing infectious pulmonary complications for critically ill patients.

Enteral Nutrition

Enteral nutrition has been proposed as another means of prophylaxis of SRMD. The theoretical basis for this is multifaceted. First, most enteral feeding solutions are alkaline and have the potential to raise intragastric pH, although studies indicate a variable effect on gastric pH in actual practice [41]. Further, enteral tube feeds increase mucosal blood flow in animal models [41], which could be attractive if applicable to humans, because this could potentially counteract pathophysiologic events hypothesized to initiate SRMD.

Despite these theoretical advantages, studies evaluating enteral nutrition for SRMD prophylaxis have had mixed results [42]. A meta-analysis of studies assessing stress ulcer prophylaxis showed no additional benefit with an H2RA in patients receiving enteral nutrition, suggesting the feeding itself was protective and that further acid suppression did not have additional impact [43]. However, this study has been criticized for methodologic issues in identifying which patients received parenteral nutrition [13].
Although some form of stress ulcer prophylaxis has been shown to prevent clinically significant GI bleeding, medications used for prophylaxis are not without side effects. With much lower incidence of stress ulcer bleeding in the present day, universal use of prophylactic agents may shift the risk to benefit ratio toward risk rather than benefit; however, these concepts remain controversial and need further discussion [20].

The major cause for concern with stress ulcer prophylaxis is nosocomial infection, especially nosocomial pneumonia and Clostridium difficile–associated diarrhea (CDAD). The acid environment in the stomach acts as an effective barrier to pathogens. Acid suppression, both with H2RAs and PPIs, has been shown to increase bacterial colonization in the stomach and duodenum, with a more profound effect seen with PPIs [44]. Subsequent aspiration of these pathogenic bacteria into the lungs could potentially lead to pneumonia in critically ill patients. With no impact on gastric acidity, sucralfate is not believed to increase rates of nosocomial pneumonia, making this agent a potentially attractive alternative in this setting. However, studies examining the incidence of nosocomial pneumonia with stress ulcer prophylaxis using some form of acid suppression have presented mixed results. A large review by Cook et al. showed no statistically significant increase in pneumonia with the use of H2RA as prophylaxis, when compared to placebo, antacids, or sucralfate [17]. Three of four meta-analyses evaluating PPIs as stress ulcer prophylaxis found no significant increase in rates of pneumonia compared to patients on H2RA [36–38], with only one meta-analysis showing an increase in risk [29]. Another study evaluating PPI versus H2RA in over 20,000 cardiac surgery patients found a slight increase in risk of pneumonia with PPI over H2RA [45]. Finally, a recent meta-analysis including over 1,000 patients showed no increase in rates of nosocomial pneumonia in patients receiving stress ulcer prophylaxis [25].

Acid suppression therapy, particularly PPI therapy, has been linked to CDAD. Incidence of CDAD has been reported to be higher with PPI therapy compared to H2RA with an OR of 3.0, which was higher in that study than the risk attributed to various classes of antibiotics. Another study suggested that the duration of PPI therapy is an independent predictor of CDAD [23,29,46].
IMPACT ON MORTALITY AND RISK TO BENEFIT ANALYSES

Weighing the beneficial effects of stress ulcer prophylaxis against potential adverse events attributed to prophylaxis can be a difficult balancing act. A crude but effective measure is to evaluate the impact that stress ulcer prophylaxis has on all-cause mortality. Studies evaluating this endpoint almost universally reveal no differences in mortality between the various stress ulcer prophylaxis agents or against no prophylaxis [17,25,36–38]. A single study by McLaren et al. showed an increase in mortality with PPIs compared to H2RAs, although the design of this study makes causation difficult to determine [13,29]. Although the lack of mortality benefit appears disheartening, this must be interpreted in light of the knowledge that bleeding from SRMD by itself is not associated with an increase in mortality when controlled for comorbid factors; in contrast, this impacts morbidity and length of hospital stay. Therefore, intervention only intended to prevent bleeding will not necessarily impact the comorbid severe disease processes leading to death.
INAPPROPRIATE USE OF STRESS ULCER PROPHYLAXIS

A consequence of the widespread acceptance of acid suppression for stress ulcer prophylaxis is the fact that acid suppression is used in situations where it is not indicated. In order to shift the risk to benefit ratio toward benefit, use of acid suppression should be restricted to patients with established risk factors for SRMD (Table 204.1). Despite this, inappropriate use of acid suppression occurs frequently in the ICU setting, continuing after transfer out of the ICU and after discharge from the hospital. In the ICU, inappropriate use of acid suppression (defined as use without significant risk factors for SRMD) has been shown to occur in 32% to 68% of patients [22,47,48]. When acid suppression is initiated, a majority remain on these agents after discharge from the ICU, largely when risk factors for their use (if ever present) have resolved [48,49]. Finally, approximately 20% to 50% of patients started on acid suppression in this setting are discharged with instructions to continue on this regimen without an appropriate indication [47–50]. Beyond increasing risk for adverse events, inappropriate use of acid suppressants and stress ulcer prophylaxis can be associated with a significant financial burden [47,50,51].

Based on this data, it is evident that further education of health care personnel regarding appropriate use of stress ulcer prophylaxis is warranted. Indeed, such educational interventions of varying methodology have proven successful in individual medical centers in reducing inappropriate use and controlling costs [52–55]. However, a multicenter survey of stress ulcer prophylaxis usage found no difference in inappropriate use of prophylaxis in those that had institutional stress ulcer prophylaxis guidelines compared to those that did not, suggesting that guidelines alone may not be sufficient [22].

Determination of appropriateness of stress ulcer prophylaxis necessitates in-depth understanding of risks, benefits, and limitations, with special attention to restricting use to active disease conditions where prophylaxis has been shown to be beneficial (Table 204.1). Appropriate use is also dependent on knowing when to stop prophylaxis when risk factors have resolved. Given the multiple factors involved in decision-making, it is not surprising that the guideline-based approach has led to overuse of prophylaxis. On the contrary, appropriate use relies on critical thinking, discretion, and vigilance on the part of the prescriber, which must occur on a case-by-case basis.
MANAGEMENT OF STRESS-RELATED GI BLEEDING

When bleeding does occur, management should follow algorithms laid out for non-variceal upper GI bleeding [56]. Three basic principles are followed: adequate resuscitation, timely endoscopy, and appropriate monitoring postendoscopy. Resuscitation consists of administration of intravenous fluids and appropriate use of red blood cell transfusions. A substantial body of literature exists in supporting a restrictive transfusion strategy of limiting transfusion to settings where hemoglobin levels drop below 7 g per dL [57,58]. PPI therapy is indicated in this setting because it decreases high-risk stigmata (active bleeding, nonbleeding visible vessel, adherent clot) on upper endoscopy and reduces need for endoscopic hemostasis; however, mortality, risk of rebleeding, or need for surgery are not impacted [59]. Timing of endoscopy is dependent on the overall status of the patient; scoring systems such as the Rockall and Blatchford scores can guide decision-making [60,61]. Current guidelines recommend performing upper endoscopy within 24 hours of onset of GI bleeding, except in the case of a high-risk patient (defined as Blatchford score >12), when endoscopy within 13 hours may improve mortality [56,62]. Following endoscopy, PPI should be administered intravenously, with either bolus dosing or continuous infusion for 72 hours if high-risk stigmata are present [56]. If there is evidence of recurrent bleeding, repeat endoscopy should be performed because this has shown to be effective up to 73% of the time [63]. Transcatheter embolization of bleeding vessels is an additional measure that can be useful for peptic ulcer bleeding, but this approach cannot be recommended for stress ulcer bleeding because bleeding tends to be diffuse rather than focal. Surgery can be considered; however, rates of rebleeding and mortality are extremely high in critically ill patients undergoing total or partial gastrectomy [64,65].
SRMD results from the breakdown of the gastric mucosal barrier in the setting of critical illness. Multiple factors contribute to the pathophysiology, including impaired blood flow to the stomach, presence of inflammatory cytokines, and reperfusion injury. The end result is damage to the intricate gastric mucosal defense mechanisms and exposure of the mucosal cells of the stomach to the caustic effects of gastric acid and pepsin. Over time, this leads to erosions, ulceration, and eventually, to bleeding. Prophylaxis focused on reducing acidity of gastric secretions and as a whole is successful; existing evidence supports the use of H2RAs. Despite a more profound effect on gastric acid secretion, PPIs have not been definitively shown to be better than H2RAs in preventing stress ulcer bleeding. Regardless of the agent used, stress ulcer prophylaxis should only be used for those conditions shown to increase the risk of bleeding (Table 204.1) and should be discontinued once these conditions have resolved. When bleeding occurs, proper therapy consists of adequate resuscitation, timely endoscopic intervention, and close monitoring following endoscopy. A summary of evidence-based guidelines for SRMD is provided in Table 204.2. These therapies and interventions, complemented by other advances in ICU care, have decreased incidence of stress ulcer bleeding and SRMD. Because our understanding of the pathophysiology and treatment of this condition continues to progress, better forms of prophylaxis and therapy could further reduce the incidence and morbidity of this condition.

Sucralfate and enteral feeding may provide some degree of protection from bleeding.

Acid suppression, especially with PPIs, is associated with an increased risk of Clostridium difficile–associated diarrhea and potentially, nosocomial pneumonia.

Stress ulcer prophylaxis likely has no impact on all-cause mortality.

Inappropriate use of stress ulcer prophylaxis is common and is associated with increased costs.

GI, gastrointestinal; H2RAs, histamine-2 receptor antagonists; ICU, intensive care unit; PPIs, proton pump inhibitors.

Gastrointestinal Motility for the Critically Ill Patient

The motility of the gastrointestinal tract is a series of coordinated functions that propels its contents through the precise regulation of neural, chemical, and endocrine signals. Although a detailed review of the physiology of motility is beyond the scope of this chapter, it is important for the critical care provider to understand that the closely coordinated movements of the gastrointestinal tract, from mouth to rectum, can frequently be disrupted and deranged in the setting of severe illness.

When systemic illness strikes, such as severe sepsis, the bowels are not a teleologic priority. Rather, physiologic reserve shifts away from the gastrointestinal tract to critical organs such as the lungs, brain, and cardiovascular system, resulting in significant dysfunction and possibly damage of the gastrointestinal tract. This presents most often as delayed transit, or ileus, which may occur at any level of the gastrointestinal tract leading to a number of clinically significant consequences such as gastroesophageal reflux, gastroparesis, abdominal pain and distention, obstipation, and even bowel ischemia and perforation.

Because derangements of gastrointestinal motility are extremely prevalent in the critically ill, providers must be prepared to identify and treat these morbid, and sometimes fatal disorders. Although there has been surprisingly little research dedicated to understanding the pathophysiologic basis of motility abnormalities in the critically ill patient [1], there have nonetheless been several advances in the prevention and treatment of these disorders. This chapter focuses on the clinical presentations of the common motility disorders of the critically ill patient, including gastroesophageal reflux disease (GERD), gastroparesis, ileus, and colonic pseudo-obstruction, and review the current evidence supporting diagnostic and therapeutic approaches for these conditions.
Critically ill patients are especially prone to developing gastroesophageal reflux and related complications, particularly aspiration and erosive esophagitis, which is one of the leading causes of inpatient upper gastrointestinal tract hemorrhage in mechanically ventilated patients, after stress-related mucosal disease [2,3]. GERD is particularly prevalent among the critically ill for several reasons (Fig. 205.1). First, critically ill patients are often in the recumbent position, which promotes acid reflux [4–6] and reduces acid clearance from the esophagus. Second, many critically ill patients are intubated, sedated, or too ill to report symptoms of acid reflux, which can thus go unrecognized until complications occur. Third, critically ill patients are more likely to have increased transient relaxation of the lower esophageal sphincter (LES), due to use of drugs (e.g., morphine, atropine, theophylline, and barbiturates) and to the frequent use of indwelling nasogastric tubes [7–9]. Critically ill patients have reduced propulsive motility in the body of the esophagus [10] and extremely low or absent LES pressures, along with superimposed cough or strain, as a main contributor to GERD [11]. Fourth, critically ill patients often develop concomitant gastroparesis (see following discussion) from a host of factors, which, in turn, favors retrograde flow of gastric contents toward the distal esophagus. Taken together, these multiple mechanisms concur to clinically significant acid reflux and to its related complications.
Several nonpharmacologic steps should be taken in the critical care setting to minimize complications of acid reflux in the critically ill patient. First, patients should be kept in the semi-recumbent or upright position. This maneuver can minimize acid stasis in the distal esophagus and improve emptying of stomach contents, thereby reducing complications of acid reflux [4,5]. The effectiveness of this maneuver alone for patients who are mechanically ventilated remains controversial [5,6]. Another step is to minimize the use of nasogastric tubes. Data indicate that indwelling nasogastric tubes promote GERD and subsequent microaspiration of bacterially contaminated contents into the lower airways [7–9]. Thus, gastroesophageal reflux also can lead to nosocomial pneumonia [12,13]. Results from a small ($n = 17$) randomized trial suggest that the nasogastric tube size (i.e., 2.85 mm vs. 6.0 mm) does not appear to reduce GERD [9], although clearly this study was not powered to demonstrate statistically significant differences in clinically relevant outcomes (such as bleeding or pneumonia). Although placement of a gastrostomy tube in patients undergoing prolonged mechanical ventilation may reduce GERD and its complications, this intervention is not without its own risks and side effects [14].

A key step is to minimize the use of medications known to relax the LES. Many of these agents (Table 205.1) are commonly used in the intensive care setting. It should be noted that while these agents are known to decrease LES resting pressure, their specific impact on the development of GERD complications, including erosive esophagitis or upper gastrointestinal hemorrhage is unknown. Thus, the agents listed in Table 205.1 should not be avoided on the basis of theoretical concerns alone, if their use is otherwise medically justified.

**TABLE 205.1 Classes of Medications Commonly Used in the Intensive Care Unit Setting That Relax the Lower Esophageal Sphincter**

- Anticholinergic agents
- Aminophylline
- Benzodiazepines
- $\beta$-Adrenergic agonists
Pharmacologic therapy is often necessary in the critically ill patient to reduce the potential complications of GERD. Treatment relies primarily on acid suppression. Traditionally, intravenous (IV) histamine-2 receptor antagonists (H2RAs) have served as the mainstay antisecretory therapy in the critical care setting particularly for prophylaxis against stress-related mucosal disease [15] (as opposed to GERD prophylaxis) (see Chapter 204). However, IV proton pump inhibitors (PPIs) (pantoprazole and esomeprazole) have since replaced H2RAs as the antisecretory of choice for active mucosal bleeding. IV PPIs have excellent effectiveness in reducing recurrent hemorrhage following endoscopic hemostasis for bleeding peptic ulcer [16]. Although there are limited clinical data regarding their use for erosive esophagitis, IV PPIs produce potent and longer-lasting acid inhibition [17], making them the preferred antisecretory medication in patients at risk for GERD-related complications [18].
GASTROPARESIS

Gastroparesis, or delayed gastric emptying (GE) in the absence of mechanical obstruction, may lead to several complications among critically ill patients, including malnutrition, erosive esophagitis (as previously noted), and aspiration of gastric contents with resulting nosocomial pneumonia.

As with GERD, gastroparesis arises from a confluence of several common factors (Table 205.2) in the critically ill patient, including medications (especially narcotics and anticholinergic agents), autonomic dysfunction, postsurgical states, and endocrine abnormalities, among others.

### TABLE 205.2 Common Causes of Gastroparesis in the Critically Ill Patient

| Endocrinopathies          |  |
|---------------------------|  |
| Adrenal insufficiency     |  |
| Diabetes                  |  |

| Anticholinergic agents    |  |
| Aluminum-hydroxide–containing products |  |
| β-Adrenergic agonists     |  |
| Calcium channel blockers  |  |
| Diphenhydramine           |  |
| Levodopa                  |  |
| Narcotics                 |  |
| Octreotide                |  |
| Tricyclics                |  |

| Neurologic disorders      |  |
|---------------------------|  |
| Multiple sclerosis        |  |
| Parkinson disease         |  |
| Stroke                    |  |

| Postsurgical settings     |  |
|---------------------------|  |
| Esophagectomy with gastric pull-through |  |
Patients with gastroparesis typically present with nausea, vomiting, abdominal pain, early satiety, and postprandial bloating. These symptoms can be blunted or overlooked during critical illness, given the severity of the overall clinical picture and the concomitant treatments. In patients receiving tube feeding, high gastric residuals are a common sign of delayed GE. Because the symptoms of gastroparesis are often nonspecific, the clinician should maintain a low threshold for considering the diagnosis. A combination of physical examination findings and imaging studies confirm gastroparesis and exclude competing diagnoses, including mechanical obstruction and mucosal diseases. On examination, patients with gastroparesis may demonstrate epigastric distension with tenderness but typically lack abdominal rigidity or guarding, signs of a potentially more serious acute diagnosis. The examiner should evaluate for a succussion splash by placing the stethoscope over the left upper quadrant while gently shaking the abdomen laterally by holding either side of the pelvis. A positive test occurs when a splash is heard over the stomach and favors the diagnosis of mechanical gastric outlet obstruction over gastroparesis. Of note, the maneuver is only valid if the patient has not received solids or liquids within the previous 3 hours.

Laboratory testing may help determine the underlying cause of the decreased motility. Serum electrolyte levels, serum glucose level, hemoglobin A1C level, serum cortisol level, thyroid-stimulating hormone level, amylase, and white blood cell count (screen for infection) should be measured. A host of other tests can be used in the outpatient setting to investigate chronic gastroparesis (e.g., erythrocyte sedimentation rate [scleroderma, myopathies, lupus], urinary protein [amyloidosis], chest radiography [lung cancer with gastroparesis as a paraneoplastic syndrome], and antineuronal or anti-Hu antibodies [paraneoplastic gastroparesis]), but these are rarely indicated for the critically ill patient.

Plain films of the abdomen should be obtained to evaluate for evidence of gastric distention and to screen for overt evidence of gastric
obstruction. Upper endoscopy should be considered if there is suggestion of gastric outlet obstruction, because significant amounts of retained food, feedings, and secretions can be found in the stomach even in the absence of an obstruction to the pyloric outlet. Additional imaging tests for the investigation of gastroparesis in the intensive care unit (ICU) setting are infrequently indicated. If the problem is suspected by the presentation, becomes a primary issue, and is not easily linked to other disorders, and then confirming the diagnosis by other methods may be merited once the patient leaves the ICU. Formal measurement of gastric motor function is impractical and not routine in the critical care setting. The most accepted diagnostic test, usually performed in the outpatient setting, is a scintigraphic emptying study. Most centers use a 4-hour GE test, with a ⁹⁹Tc-labeled-egg meal. In health, gastric retention of more than 10% at 4 hours suggests delayed GE [19]. Alternative diagnostic tests include newly approved stable isotope-labeled breath test ([¹³C]-Spirulina platensis GE breath test), and the wireless motility capsule. Still, the simple finding of persistent high gastric tube residuals should be sufficient to formulate a presumptive diagnosis in the critically ill patient.

Once diagnosed, a search for possible reversible causes of gastroparesis (including mechanical obstruction and medications) should be undertaken. Treatment should begin by with nutritional and dietary modifications including smaller volume, low-fat, and low-fiber meals or tube feeds [20]. Consultation with the nutrition or metabolic support services is often warranted to help select between available liquid caloric supplements. In general, parenteral nutrition should be avoided if possible. Rather, patients who need long-term nutrition support due to gastroparesis should be considered for a jejunostomy tube [21], often placed in conjunction with a gastrostomy tube for venting of the stomach [22].

Metoclopramide and erythromycin are the only currently available prokinetic medications in the United States. Other prokinetics available outside the United States include domperidone, prucalopride, and mosapride. Metoclopramide has multiple actions, including coordination of antral, duodenal, and pyloric muscle function, while simultaneously serving as a centrally acting antiemetic [23,24]. Metoclopramide can be administered orally, intravenously, rectally, and subcutaneously. In the critically ill patient, metoclopramide typically is dosed at 10 to 20 mg IV every 6 hours. The major disadvantage of IV bolus dosing is that plasma levels are often erratic, largely because levels peak rapidly and the half-life is short. Subcutaneous dosing (two to four times per day in 2-mL aliquots) has been promoted as an alternative route, as it is associated with more stable plasma levels [25]. Although the tardive dyskinesia side effects have been known for decades, the Food and Drug Administration (FDA) recently issued a warning in reference to metoclopramide. Other
neurologic side effects include akathisia, sedation, and depression, can impact up to 30% of patients [26]. Reducing the dose and rate of IV infusion may reduce frequency of neurologic side effects.

Erythromycin prokinetic effects are due to its binding to the motilin receptor in the stomach, inducing high-amplitude gastric contractions [27,28]. The preferred route of administration is IV at low doses (e.g., 100 to 200 mg every 6 hours). Erythromycin may be used in combination with metoclopramide for patients with an incomplete response to either agent alone. A randomized-crossover study using $^{13}$C breath testing to assess response in ventilated, critically ill patients, showed combination of metoclopramide IV 10 mg every 6 hours and continuous erythromycin infusion 10 mg per hour was most effective at improving GE rate [29]. Oral dosing of erythromycin (125 to 250 mg twice daily) is effective in diabetic patients and has also shown benefits in reducing high tube feed residuals [30]. Unfortunately, long-term use of erythromycin leads to tachyphylaxis from downregulation of motilin receptors [28] and also is associated with antimicrobial resistance.

Another therapy sometimes used for gastroparesis is neuroenteric stimulation (i.e., gastric pacing). However, this treatment is available at only limited centers and is rarely used in critically ill patients. Pyloric botulin toxin injection has not been shown to be effective in gastroparesis and its role in the critically ill patient is unknown [31]. Manipulation of gastrointestinal hormones responsible for delayed GE, such as cholecystokinin, peptide YY, and glucagon-like peptide 1, has been proposed. However, pharmacologic agents with adequate selectivity and bioavailability are currently not available and still under investigation [32].
ILEUS

Any disease state affecting neurohormonal mediators, vascular perfusion, electrolyte balance, and muscular contraction has the potential to affect the coordinated propulsive small and large intestinal motility, resulting in ileus. The postoperative state, inflammation, metabolic derangement, neurogenic impairment, and drug-induced aperistalsis are all common occurrences in the ICU. Patients typically present with abdominal distention, obstipation, nausea, vomiting, abdominal pain, and high tube feed residuals.

Distinguishing ileus from small bowel obstruction is critical, as prolonged mechanical obstruction can lead to bowel ischemia and peritonitis. Table 205.3 compares classical physical examination and radiographic findings of adynamic ileus and small bowel obstruction. These conditions share many clinical manifestations. Peritoneal signs and auscultation of high-pitched bowel sounds favor small bowel obstruction, whereas a silent bowel suggests ileus. Although the skilled clinician often can reliably distinguish small bowel obstruction from ileus on the basis of history and physical examination alone, plain abdominal radiographs may serve to confirm the clinical impression. Ileus typically is characterized by the presence of both small and large bowel dilatation, the presence of gas throughout the bowel and into the rectum, lack of a luminal radiographs may serve to confirm high pitched bowel sounds, small bowel obstruction typically presents with small bowel distention in the absence of colonic gas, a paucity of gas in the rectum, air fluid levels on upright positioning, and with evidence of a luminal transition point.

Despite the stereotypical features of small bowel obstruction and ileus, plain film imaging does not always provide a definitive diagnosis, as long-standing ileus or partial small bowel obstruction may appear similar on abdominal imaging. In addition, late-stage mechanical obstruction may lead to exhaustion of intestinal propulsive activity, resembling adynamic ileus without high-pitched bowel sounds and a similar air distribution pattern on plain abdominal X-rays. In cases in which the plain films are inadequate, contrast-enhanced computed tomography (CT) should be considered [33]. A CT scan may provide additional information to complement the clinical picture, such as the presence or absence of intra-abdominal inflammation (e.g., pancreatitis, abdominal abscess) or retroperitoneal pathology.

---

[33]
Once small bowel obstruction has been excluded, the next step is to identify and treat reversible causes of ileus. Common causes in the critically ill patient include electrolyte abnormalities, sepsis, inflammation, postoperative hypomotility, and medications (Table 205.4), initial laboratory studies should include serum potassium, magnesium, calcium, bicarbonate, lipase, blood urea nitrogen, creatinine, and white blood cell count. Medications should be carefully reviewed, and potentially causative agents discontinued or limited if otherwise warranted. There are no specific rules about how and when to discontinue medications in the setting of ileus, especially when necessary pain medications (e.g., narcotics) are involved. Ultimately, the decision rests on a careful balance of clinical factors and meticulous attention to the progress and clinical sequelae of the ileus. In particular, if there is concomitant evidence of significant cecal or large bowel distention to suggest colonic pseudo-obstruction and impending perforation, and then all the medications potentially contributing to aperistalsis should be discontinued.

In contrast, if there are no clinical signs of deterioration and no worsening on serial abdominal X-rays, the ileus is nonprogressive and
stable, and a supportive, conservative treatment is preferred, the
treatment plan should include adequate IV hydration, electrolyte
replacement, and treatment of the underlying condition(s), with close
clinical and radiologic follow-up. There is little evidence [34–44] to
support insertion of a nasogastric tube for decompression of prolonged
ileus and worsening abdominal distention; however, when vomiting is
present, this is routinely performed. One caveat to this widespread
approach is the trend in favor of more atelectasis and pneumonia in
patients receiving nasogastric decompression in randomized controlled
trials [34–44]. Data from postoperative patients do not support the need
for nasogastric tube decompression [37,45].

Unfortunately, pharmacologic treatments for ileus remain limited.
Promotility agents are generally ineffective for most cases of ileus.

Patients with an ileus who are receiving narcotics may be experiencing
dysmotility from the narcotics. Opioid-induced bowel dysfunction can
occur after the initial dose of opioids and not resolve for some time after
therapy is discontinued. Unlike many of the other side effects from
narcotics, the constipating effect and other bowel dysfunctions do not
decrease with prolonged use [46]. Although stool softeners, stimulant,
and osmotic laxative are traditionally used, a subset of critically ill
patients will not respond to traditional measures and will go on to
develop inability to tolerate enteral feedings and laxatives [47]. Opioid
reversing agents, with limited systemic bioavailability, have been
traditionally used, such as naloxone, naltrexone, and nalmefene.
However, early transit across the blood–brain barrier by these agents
causd concomitant analgesia reversal and the onset of opioid
withdrawal, without consistent restoration of peristalsis [48]. Newer
peripherally acting mu opioid receptor antagonists (PAMORAs) do not
substantially cross the blood–brain barrier. Methylnaltrexone and
naloxegol are efficacious in treating opioid-induced constipation [49].
Methylnaltrexone is available subcutaneously, which is advantageous in
critically ill patients. Naloxegol is an oral PAMORA approved by the FDA
for opioid-induced constipation. There are no systematic data on the use
of naloxegol in the intensive care or postoperative setting. Its oral
administration, favorable tolerability and pharmacokinetic profiles
support potential clinical utility in opioid-induced ileus [50].

Postoperative ileus has multiple pathophysiologic causes including
surgical stress hormones, activation of the endogenous opioid system,
exogenous opioids given for pain, and inflammation compounding
imbalance in fluid and electrolytes.

Traditional prokinetics have been used for reversal of postoperative
ileus. Although metoclopramide has proven efficacy in the foregut, it
provides little or no benefit for postoperative ileus [51–55]. There have
been few studies of metoclopramide in postoperative ileus, so it is
difficult to conclude whether its ineffectiveness in postoperative ileus extends to other forms of ileus. Similarly, randomized controlled trials of erythromycin in postoperative ileus demonstrated minimal, if any, benefit [56]. The somatostatin analog, octreotide, has been used empirically, although no good randomized controlled data exist for its use in humans with postoperative ileus, and there are potential detrimental effects on GE with octreotide that need to be considered before administering in severe whole gut dysmotility.

One trial of 65 postcolectomy patients demonstrated efficacy of methylnaltrexone (see earlier) 0.3 mg given intravenously every 6 hours to achieve a first bowel movement and to hasten discharge from the hospital [57]. These observations support a role for opioid reversal even in the absence of a previous effect of exogenous opioids on gut motor function. Larger trials on methylnaltrexone are needed.

Another opioid antagonist, the selective $\mu$-opioid receptor antagonist, alvimopan, is approved by the FDA for the treatment of postoperative ileus [58,59]. Oral alvimopan is administered preoperatively and postoperatively. In one randomized, controlled, blinded clinical trial of postoperative ileus, alvimopan, 6 mg twice daily, led to a faster passage of flatus (by 21 hours), earlier initiation of bowel movements (by 41 hours), and faster time to discharge (by 23 hours) than placebo [58]. A subsequent larger trial in 510 patients demonstrated similar results [59]. These dramatic effects in postoperative ileus set the stage for the use of alvimopan in other forms of ileus. In a study of 522 patients with noncancer pain requiring an equivalent dose of narcotics more than 30 mg of oral morphine daily, alvimopan was superior to placebo in increasing bowel movement frequency and other endpoints correlated to severe opioid-induced constipation. Although alvimopan has been shown to be effective for opioid-induced constipation it is not FDA approved for this indication due to concerns of cardiovascular side effects demonstrated in one study [60].
ACUTE COLONIC PSEUDO-OBSTRUCTION
(OGILVIE SYNDROME)

Acute colonic pseudo-obstruction, or Ogilvie’s syndrome, is characterized by marked dilatation of the cecum and ascending colon in the absence of mechanical obstruction (Fig. 205.2). Similar to ileus, colonic pseudo-obstruction generally occurs in critically ill patients with sepsis, recent surgery, electrolyte abnormalities, and trauma, among other conditions. The diagnosis rests on radiographic evaluation of the cecum, where a diameter of more than 9 cm suggests evidence of pseudo-obstruction in the absence of a mechanical obstruction. This threshold is somewhat arbitrary and is based on an early series from 1956 that linked this diameter with clinically significant sequelae, namely colonic perforation [61]. More recent case series suggest that a cecal diameter exceeding 12 cm correlates most highly with bowel perforation and should serve as a critical threshold to track in patients with suspected pseudo-obstruction [62,63].
The exact mechanism by which cecal dilatation occurs remains unclear. There are two competing theories [64]. The first theory, originally postulated by Dr. Ogilvie in 1948 [65], suggests that sympathetic drive to the enteric nervous system is interrupted, thereby promoting unopposed parasympathetic stimulation. This, in turn, could promote unabated distal colonic luminal contractions and a potential source of obstruction. The second theory, espoused by Hutchinson and Griffiths [66], contends that colonic pseudo-obstruction arises from a combination of sympathetic overdrive and parasympathetic suppression, both described in the setting of physiologic stress, thereby leading to colonic hypomotility and eventual paralysis. The proven effectiveness of neostigmine for colonic pseudo-obstruction (see following discussion) supports the validity of the latter theory. In contrast, there are few
physiological data to support Ogilivies’ original concept of sympathetic interruption. It should be noted that the autonomic nervous system is not the only player in colonic motility. Other factors including neurohormones and gut peptides play a significant role in regulating motility in the gastrointestinal tract.

The clinical presentation of acute colonic pseudo-obstruction is typical of obstructive colonic processes, with the patient demonstrating marked abdominal distention, nausea, vomiting, and abdominal pain. If left untreated, colonic pseudo-obstruction can lead to ischemia, perforation (in approximately 3% of cases overall), peritonitis, and death [67–70]. Thus, the clinician must keep a high index of suspicion for colonic pseudo-obstruction in patients with risk factors, as the consequences of late diagnosis can be grave.

Fortunately, conservative measures are sufficient in most cases, and the cecal dilatation resolves spontaneously. Conservative measures consist of ceasing oral intake, frequent repositioning of the patient, and treating potential underlying causes of dysmotility (as with ileus). Although nasogastric tubes are often employed in cases of colonic pseudo-obstruction, there are no data from randomized controlled studies to support its effectiveness in reducing clinically significant endpoints. Because nasogastric decompression has limited, if any, role in ileus [44–49,51–54], there is little a priori reason to believe that the maneuver would be of benefit in colonic pseudo-obstruction, a condition that is even more distal to the tip of a nasogastric tube than ileus. In contrast, case series do support the effectiveness of colonoscopic decompression, which reduces the cecal diameter in nearly 70% of patients [67,70]. Unfortunately, colonoscopic decompression alone is often short lived, and recurrent distention occurs in approximately half of patients [64,67]. Thus, colonoscopic decompression usually is accompanied by placement of a rectal tube or stent with its proximal tip in the ascending colon. Data from a small controlled clinical trial suggest the efficacy of colonic decompression can be maintained after initial success by administration of polyethylene glycol (PEG) balanced solutions, resulting in increased stool output and flatus, and in reduction of visceral dilation [71]. However, while colonoscopic decompression and tube placement is conceptually attractive, the procedure is challenging and often unsuccessful and it must be conducted in an unprepared bowel without the benefit of full air insufflation.

In patients failing to respond to conservative measures after 24 to 48 hours, including correction of electrolyte abnormalities, IV hydration, correction of underlying medical causes, and minimization of culprit medications, pharmacologic therapy is generally warranted. Moreover, if at any time the cecal diameter exceeds 12 cm, or if there is evidence of worsening clinical status, and then aggressive treatment should be
pursued immediately, because these findings constitute a gastroenterologic emergency, which mandates early consultative involvement of a surgeon. In patients with markedly dilated large bowel, some specialists would defer even an initial attempt at colonoscopic decompression to a trial of medical therapy. The acetylcholinesterase inhibitor neostigmine increases the postsynaptic concentration of acetylcholine, thereby favoring a boost in the deranged colonic motor function. Neostigmine is effective in colonic pseudo-obstruction, and its IV administration has been accepted as initial therapy. This recommendation is largely based on a pivotal controlled trial in which 10 of 11 patients randomized to receive neostigmine had prompt evacuation of their colonic contents and normalization of their cecal diameter, whereas none of 10 patients randomized to placebo had these outcomes [68]. Moreover, all of the patients in the placebo arm achieved a response when crossed over to neostigmine in an open-label fashion. The dosage used was 2 mg IV in one infusion followed by an additional 2 mg infusion 3 hours later if there was no initial response or adverse event. Being an anticholinesterase inhibitor, neostigmine has an array of well-defined cholinergic side effects, including bronchoconstriction, abdominal cramping, hypersalivation, diaphoresis, and bradycardia. Hemodynamically relevant side effects, including cardiac arrest and cardiovascular collapse, can occur, requiring neostigmine to be administered in a monitored setting. It is contraindicated in patients with bradycardia, active bronchospasm, and mechanical bowel obstruction. Existing electrolyte imbalances and use of antimotility agents were predictors of poor response to neostigmine. Patients with postoperative colonic ileus had the best response rate [69]. According to a retrospective review of 151 patients, additional predictors of response to neostigmine after failure of conservative management were female gender and older age [72]. The combined administration of 2 mg neostigmine with glycopyrrolate, an anticholinergic agent that has limited activity on the muscarinic receptors of the colon and has the potential of reducing the incidence of cholinergic side effects of neostigmine, has been evaluated in a randomized, controlled study of 13 patients with neurogenic bowel using video fluorographic assessment of evacuation [70]. The neostigmine Korsombination resulted in bowel evacuation with significantly less bradycardia and increase in airways resistance than with neostigmine alone, suggesting that the coadministration would make treatment with neostigmine safer in clinical settings where cardiorespiratory function is compromised. When severe colonic pseudo-obstruction fails to respond to conservative measures, neostigmine, and colonic decompression, surgery must be considered. In these settings, surgery has a high morbidity and may lead to poor outcomes in patients who are already critically ill.
Indeed, case series indicate that one quarter of patients with colonic pseudo-obstruction die in the perioperative period, even in the absence of bowel perforation [65], although the presence of underlying critical illness is arguably the strongest predictor of such a guarded prognosis. Alternatively, endoscopic cecostomy with placement of a percutaneous tube using a modified Seldinger technique similar to percutaneous gastrostomy has been described [73].
SUMMARY

Gastrointestinal motility requires coordinated neural, chemical, and endocrine signals. Systemic illness often deranges motility, leading to syndromes such as GERD, gastroparesis, ileus, and colonic pseudo-obstruction. Although there are no randomized trials to support IV PPI therapy versus IV H2RA therapy in the critically ill patient, there is a biologic rationale to consider using IV PPI therapy.

In general, the critical care provider should aim to maintain the appropriate physiologic environment (e.g., normalize electrolytes imbalances and maximize blood flow) and limit known causes of dysmotility (e.g., narcotics and anticholinergics) to ensure at least some level of gastrointestinal motor function. When these measures fail, providers should employ therapies that are supported by the highest level of evidence, namely randomized controlled trials, when available (Table 205.5). Among the therapies described in this chapter, there is high level of evidence to support neostigmine in colonic pseudo-obstruction, alvimopan in postoperative ileus, methylnaltrexone in opioid-induced bowel dysfunction, and good evidence supporting the use of metoclopramide and possibly erythromycin in gastroparesis. Future research for critically ill and injured patients should focus on the effects of novel medications under development on endpoints of motor function, morbidity, and mortality, with fewer systemic side effects and an excellent risk profile.

**TABLE 205.5 Summary of Evidence-Based Management Recommendations**

- Treatment and prevention of complications from gastroesophageal reflux should include encouraging the semirecumbent or upright position, avoidance of nasogastric tubes, and use of potent antisecretory therapy, such as intravenous proton pump inhibitors.
- Medical therapy for gastroparesis often is ineffective, although modest benefits are seen with metoclopramide (especially subcutaneous administration) and erythromycin.
- Evidence for placement of a nasogastric tube for decompression in postoperative ileus is weak, as indicated by meta-analyses.
• Data indicate that there is little or no benefit of metoclopramide or erythromycin in the setting of ileus.
• Methylnaltrexone is an opioid reversal agent that does not cross the blood–brain barrier and achieves sustained laxation in opioid-induced bowel dysfunction.
• Alvimopan, a highly selective opioid receptor antagonist, has demonstrated excellent results in postoperative ileus in randomized controlled trials.
• Neostigmine was shown in effective medical therapy for the treatment of acute colonic pseudo-obstruction in the presence of colonic diameter >12 cm as determined by direct abdominal X-ray. Endoscopic bowel decompression with insertion of a decompression tube is an effective alternative management option.
REFERENCES

Liver function abnormalities are detected among up to 60% of intensive care unit (ICU) patients, often leading to hepatology consultation [1], and early hepatic dysfunction (serum bilirubin > 2 mg per dL within 48 hours of admission) is a specific and independent risk factor for poor prognosis [2]. The presentation of hepatic dysfunction ranges from simple abnormalities in biochemical tests with little impact on a patient’s clinical course to complex manifestations of liver failure that require prompt intervention because of high morbidity and mortality. Etiologies of hepatic dysfunction are many and varied. Sometimes, a detailed clinical history is sufficient to establish the cause of the derangement; however, a combination of clinical experience and judicious use of supplemental testing is required to establish a specific diagnosis and suggest a therapeutic course of action. Understanding the anatomic interactions between the liver and other organs and the physiologic principles that determine hepatic function is essential for establishing a rational therapeutic approach for each disorder. In this chapter, we outline aspects of liver physiology that are altered among critically ill patients and review common disorders of hepatic dysfunction seen in this setting. We also discuss complications of chronic hepatic dysfunction and appropriate management of critically ill patients with cirrhosis.

PHYSIOLOGIC CONSIDERATIONS

Blood Flow
In resting conditions, the liver receives 25% of the cardiac output and 10% to 15% of the total body blood volume. About 25% of the liver volume consists of blood (capacitance function). The human liver has dual blood supply. Approximately one-third of the hepatic blood flow is supplied by the hepatic artery (low-flow, high-pressure system, well-oxygenated blood) and two-thirds by the portal vein (high-flow, low-pressure system, poorly oxygenated blood). The hepatic artery supplies the capsule of the liver and bile ducts. The portal vein is formed by the splenic vein, superior mesenteric vein, and inferior mesenteric vein (it drains into the splenic vein). The left gastric vein branches from the portal vein and plays a fundamental role in the formation of esophageal varices for patients with portal hypertension. The portal vein provides venous drainage for several abdominal organs: pancreas, stomach, intestine, and spleen. Once within the liver, arterial and venous bloods mix in the hepatic sinusoids [3]. The sinusoids are involved in the exchange between the blood, space of Disse, and the hepatocytes. The blood flowing through the sinusoids is collected in the central veins and then into the hepatic veins and inferior vena cava.

The sinusoids are composed of fenestrated endothelial cells, Kupffer cells, stellate cells, and natural killer (NK) cells. Endothelial cells represent 50% of the sinusoidal cells. They contain numerous fenestrae (not uniform in size or distribution) with dynamic structure and function. Endothelial cells have several functions including endocytosis, secretion (interleukins, interferon, eicosanoids, endothelin, and nitric oxide), and expression of adhesion molecules. Kupffer cells are phagocytic and remove infective, toxic, and foreign substances from the portal blood. They also release substances involved in the immune response by the liver. Stellate cells, also known as lipocytes, fat storing cells, or Ito cells, store fat vacuoles (major storage sites of retinoids). They have contractile activity regulating the blood flow through the sinusoids. The NK cells, also known as Pit cells, are liver-associated lymphocytes with azurophilic granules having lysosomal activity [4,5].

Blood flow through the liver varies considerably under different physiologic conditions. In the normal state, the liver extracts less than half of its supplied oxygen (4.6 mg/min/100 g liver). Thus, in most conditions of increased oxygen demand, the liver can increase oxygen extraction without an alteration in blood flow [6]. Regulation of total hepatic blood flow occurs primarily at the level of the hepatic artery. If portal venous inflow decreases, compensation is accomplished through vasodilatation of the hepatic artery. However, reductions in mean arterial pressure below 50 mm Hg exceed the capacity of the autoregulatory mechanisms to maintain adequate liver perfusion [7].

Bilirubin Metabolism
The majority of bilirubin (80%) is generated from the breakdown of heme released by senescent red blood cells. Unconjugated bilirubin (indirect bilirubin) circulates bound to albumin before entering the hepatocyte through an active process mediated by transporter proteins. Once inside the hepatocyte, unconjugated bilirubin is transferred to the smooth endoplasmic reticulum, where it is conjugated with glucuronic acid (conjugated or direct bilirubin) and, in turn, secreted into the biliary canaliculi by a pump called multidrug resistance protein 2. Once in the gastrointestinal (GI) tract, bilirubin is deconjugated by gut bacteria enzymes and oxidized to stercobilin and eliminated in the stool. Stercobilin is also reabsorbed in the small intestine, passes the liver, and is reexcreted through the kidney (urobilinurib) in the so-called enterohepatic circulation [8].

Unconjugated hyperbilirubinemia results from increased bilirubin production (e.g., ineffective erythropoiesis, hemolytic disorders), impaired uptake (e.g., Gilbert syndrome, use of certain drugs such as rifampin), or defective conjugation (e.g., Gilbert syndrome, Crigler–Najjar syndrome types I and II). Conjugated hyperbilirubinemia results from a wide spectrum of familial (Dubin–Johnson syndrome and Rotor syndrome), hepatocytic, and biliary disorders that are associated with a benign course, acute or chronic liver cell damage, cholestatic injury, or biliary tree obstruction (intrahepatic or extrahepatic). Cholestasis of an ICU patient may be seen with sepsis, postoperatively after multiple blood transfusions, with severe alcoholic hepatitis, as a result of idiosyncratic reaction to medication (often antibiotics) or drug-induced liver injury (DILI) or while receiving total parenteral nutrition (TPN). Among adults, primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are the most common causes of chronic cholestatic liver disease. Patients with decompensated cirrhosis are often jaundiced. Less commonly observed cholestatic chronic liver conditions such as intrahepatic cholestasis of pregnancy, progressive familial intrahepatic cholestasis, and benign recurrent intrahepatic cholestasis may require expert consultation for diagnosis [9,10].

Drug Metabolism

The liver is positioned strategically between the digestive tract and the systemic circulation. Only those substances absorbed by the oral mucosa and the rectum bypass the liver, reaching the systemic circulation directly. Several diverse pathways participate in the metabolism of drugs and toxins by the liver. Three main enzymatic pathways participate in drug metabolism: oxidation, hydrolysis, and reduction, catalyzed by oxidoreductases, hydrolases, and transferases. The oxidoreductases and hydrolases catalyze phase I reactions that increase polarity (or water
solubility) of substances and potentially generate toxic metabolites. The transferases catalyze phase II reactions through conjugation and produce less toxic and biologically less active products when compared to the parent compound. The most important drug oxidation system is the P450 system (the electron transport chain associated with the microsomal system). The central protein in this system is cytochrome P450, a hemoprotein [11]. The primary reactions, biochemical or physiologic changes, and toxic consequences to the liver of drug and toxin exposure may be variable and in part dependent on the interaction with the host [12–14].

Hemostatic Function

The liver is the primary site of synthesis of most of the coagulation factors and the major inhibitors of the activated coagulation cascade. The synthesis of procoagulant factors II, VII, IX, and X and anticoagulant factor proteins C and S depends on the presence of vitamin K. The adequacy of hepatic synthetic function can be estimated by the prothrombin time (PT) or international normalized ratio (INR). In the presence of liver disease, there is reduced synthesis of clotting factors and inhibitors of coagulation. The synthesis of abnormal clotting proteins with anticoagulant activity leads to disseminated intravascular coagulation (DIC) and enhanced fibrinolytic activity. In addition, thrombocytopenia, associated with portal hypertension and hypersplenism, and thrombocytopathy are usually identified in patients with end-stage liver disease. Consequently, most patients with liver disease have some measurable defect in hemostasis involving the coagulation system, fibrinolytic system, platelets, and reticuloendothelial system (Kupffer cells). The resultant clinical impact of this bleeding diathesis, however, is of variable importance. When and how the physician institutes therapeutic or prophylactic hemostatic interventions is debated and must be tailored for each patient [15,16].
Ischemic Hepatitis

Liver ischemia is the consequence of hypoxic liver insult and presents in the setting of reduced liver blood flow, persistent systemic hypotension, or severe hypoxemia. Common synonyms for ischemic hepatitis include acute hepatic infarction, shock liver, and hypoxic hepatitis. The hepatic insult is diffuse, noninflammatory in nature, and results in variable degrees of central vein (zone 3) necrosis and collapse. The syndrome is typically recognized through detailed clinical history and biochemical evaluation because the precipitating factor may not be apparent. Dehydration, heat stroke, hemorrhage, cardiogenic shock, acute decline in cardiac output in the absence of hypotension, traumatic shock, respiratory failure, aortic dissection, pulmonary embolus, and extensive burns have been associated with ischemic hepatitis. For patients with congestive heart failure (left ventricular failure) and chronic passive liver congestion (right ventricular failure), even minor, additional insults may precipitate liver ischemia. The incidence of ischemic hepatitis in the ICU has been reported to be approximately 2.5%, with only half with identifiable hypotensive episode, and yet the in-hospital mortality associated with ischemic hepatitis approaches 50%, highlighting the importance of clinical suspicion and recognition [17,18].

The clinical presentation is highly variable. Biochemically, there is a characteristic rapid rise in serum aminotransferases, reaching 10 to 40 times the upper limits of normal. The lactate dehydrogenase also increases dramatically, whereas abnormalities in serum bilirubin, alkaline phosphatase, and PT are less striking. Peak elevations occur in the first 72 hours. In situations in which the triggering factor resolves, normalization of laboratory tests may occur over 7 to 10 days. Other chemistry abnormalities include renal failure with increased blood urea nitrogen and serum creatinine. Patients may present with hepatic encephalopathy, mild jaundice, weakness, or general malaise. More typically, the dominant clinical features are those of the disorder that triggered the ischemic insult. The differential diagnosis includes other disorders associated with significant, rapid increases in liver enzymes, such as acute viral hepatitis, alcoholic hepatitis, and drug-induced hepatotoxicity. In only rare instances, a liver biopsy is necessary for diagnosis.

Treatment of ischemic hepatitis is directed at correction of the underlying disease or factor that initiated the liver damage. The aim of treatment is to improve cardiac output, optimize liver and peripheral
organ perfusion, and improve tissue oxygenation. The specific intervention depends on the precipitating factor and varies from case to case. Ischemic hepatitis is frequently self-limiting, and recovery is associated with normalization of the hepatic architecture. From the liver standpoint, the prognosis depends on the presence of a normal or previously damaged liver and on the etiology of the underlying disorder.

**Congestive Hepatopathy**

Congestive hepatopathy and passive hepatic congestion are interchangeable terms used to refer to the outcome of increased hepatic vein pressure from a variety of causes. The increased pressure is transmitted through the hepatic veins and venules to the hepatocytes resulting in initial damage to cells in zone 3 [19]. Additional liver damage is thought to occur from decreased hepatic flow and decreased arterial oxygen saturation [20]. The most common causes are ischemic cardiomyopathy, heart failure, valvular heart disease, restrictive lung disease, pulmonary arterial hypertension, and pericardial disease. Right-sided heart failure of any etiology (constrictive pericarditis, tricuspid regurgitation, mitral valve stenosis, or cardiomyopathy) increases the pressure of the inferior vena cava and the hepatic veins and ultimately produces liver congestion [21–23]. Although the clinical presentation of hepatic vein thrombosis (Budd–Chiari syndrome), primary thrombosis limited to hepatic venules, sinusoidal obstructive syndrome (formerly known as veno-occlusive disease), and inferior vena cava thrombosis at its hepatic portion (obliterative hepatocavopathy) may be clinically similar to congestive hepatopathy, accurate differential diagnosis is imperative. The workup of these conditions includes various imaging modalities, such as ultrasound with Doppler flow, fluoroscopic cavography, and magnetic resonance venography; at times, liver biopsy is needed for a definitive diagnosis. These medical conditions have different etiologic factors and treatment approaches [22,24–26].

The patient with liver congestion may present with signs and symptoms of right-sided heart failure and only subtle abnormalities in liver chemistries. The aminotransferases may be mildly elevated, reflecting limited degree of liver cell necrosis. Mild elevations of the alkaline phosphatase and total bilirubin are also common. In more severe presentations, the patient may be jaundiced, suggesting extrahepatic biliary obstruction. Congestive hepatopathy can eventually lead to development of hepatocellular necrosis, broad fibrous septa deposition, regenerative nodule formation, architectural derangement, and frank cirrhosis, previously termed cardiac cirrhosis. Congestion produces tender hepatomegaly, and a pulsatile liver can occur with tricuspid regurgitation. Hepatojugular reflux may be elicited, and ascites is a
frequent finding. For these patients, the ascitic fluid albumin is high (>2 g per dL); in contrast, among noncardiac cirrhosis, the ascitic fluid albumin is typically lower (<2 g per dL) [27]. The serum albumin-to-ascites albumin gradient (SAAG) is more than 1.1 g per dL for both conditions. Diagnosis rests on a combination of a high index of suspicion and studies that confirm the presence of cardiopulmonary disease. Pressure measurements through cardiac catheterization, transjugular hepatic venous pressure gradients, and cardiac imaging studies are diagnostic.

A transjugular liver biopsy, ideally obtained at the time of pressure measurements, can be helpful for difficult cases. Classical biopsy findings include centrilobular parenchymal atrophy; sinusoidal and terminal hepatic venular distention; and red blood cell congestion and extravasation into the space of Disse. In addition, perisinusoidal collagen deposition is seen with chronic congestion. Treatment is focused on management of the underlying pulmonary, cardiac, or pericardial disease and removal of precipitating causes such as medications that are negatively inotropic or nephrotoxic. In select cases, advanced heart failure therapies including ventricular assist devices (VAD) and heart transplantation can be considered. Hepatic dysfunction often improves with these therapies when cardiac in origin. Both hepatic and renal dysfunction are predictive of outcomes after VAD and heart transplantation. Cirrhosis is a contraindication to isolated heart transplantation [28–31].

Ascites is managed with diuretics, low-salt diet, or large-volume paracentesis (LVP). Transjugular intrahepatic portosystemic shunt (TIPS) is contraindicated for severe cases of congestive heart failure, tricuspid regurgitation, or pulmonary hypertension, because the marked increase in systemic venous return may precipitate an acute exacerbation of heart failure [32].

**Total Parenteral Nutrition**

TPN remains a vital medical intervention, and its use has become routine to provide nutrition to those who are unable to eat or tolerate enteral nutrition (short gut syndrome, Crohn disease, radiation enteritis, severe pancreatitis, post-op periods, etc.). Hepatobiliary dysfunction is recognized as a major adverse effect of short-term and long-term TPN use [33–35]. Variable degrees of liver dysfunction, ranging from subtle laboratory abnormalities to clinically apparent liver disease, develop among 40% to 60% of infants and 15% to 40% of adults who require long-term TPN [36,37]. The wide prevalence ranges reflect the difficulty in ascribing liver dysfunction to TPN, particularly in the ICU where the etiology of liver abnormalities may be multifactorial, including infectious,
drug-induced, or endocrine disorders. The spectrum of hepatobiliary complications attributable to TPN includes hepatic steatosis, intrahepatic cholestasis, biliary sludge, and cholelithiasis [38]. TPN-related complications are more commonly seen after prolonged periods of parenteral nutrition. Cholestasis is more commonly seen among infants than adults, whereas biliary sludge and cholelithiasis affect both the groups. Progression to cirrhosis and portal hypertension is rare and occurs more frequently among infants and neonates than adults [39].

Most patients with hepatic steatosis are asymptomatic, and liver enzyme levels usually peak within 1 to 4 weeks of TPN initiation. The elevation is often transient, and complete resolution may occur spontaneously despite continued use of TPN. With the development of currently accepted protocols for caloric intake, including lipids as an alternative calorie source, the prevalence of liver steatosis has declined significantly [40–42].

Cholestasis is uncommon among adults on short-term TPN (<3 weeks) [38]. In contrast, among adults on long-term TPN, cholestasis has been reported in up to 65% [36]. Large doses of lipid emulsion (>1 g/kg/d), short bowel syndrome (small bowel remnant < 50 cm), bacterial translocation, hypoxia, and sepsis have been associated with the development of chronic cholestasis [39]. The major concern with cholestasis in those receiving long-term TPN is the risk of progression to chronic liver disease and liver failure. In this setting, TPN may need to be discontinued. TPN-dependent individuals with intestinal failure, who have persistent liver enzyme abnormalities or evidence of impending liver failure, should be considered for isolated intestine transplantation. In the presence of end-stage liver disease, however, combined intestine and liver transplantation (LT) may become necessary. Survival postisolated intestine or combined intestine–liver transplantation is 50% at 5 years, making this a viable therapeutic option [42]. Ursodeoxycholic acid (10 to 30 mg/kg/d) has shown variable success for preterm infants and adults with TPN-induced cholestasis by improving bile flow and reducing gallbladder stasis [43].

Biliary sludge develops in 50% to 100% of individuals after more than 6 weeks on TPN [38,44]. Again, clinical manifestations vary significantly. Some patients may be asymptomatic, whereas others develop striking gallbladder distention, acalculous cholecystitis, or gallstone cholecystitis. Decreased release of cholecystokinin (biliary stasis), use of narcotics (increase in bile duct pressure), and increased bile lithogenicity are contributing factors. Early introduction of oral feeding decreases the
incidence of biliary complications. Changes in the rate or composition of the TPN infusion to stimulate gallbladder contraction are impractical and not universally successful [45,46]. Acute acalculous cholecystitis is a serious condition that requires the use of broad-spectrum antibiotics, a percutaneous drainage procedure, or a surgical intervention (i.e., cholecystectomy).

Timing of initiation of parenteral nutrition in the ICU remains controversial. Although prior observational data supported early enteral and/or parenteral feeding, recent data suggests no mortality difference when earlier initiation (within 48 hours) was compared with a late initiation (after day 8). Furthermore, the late initiation group had a lower incidence of cholestasis and ICU-related infections, providing further support for a delayed strategy [47,48].

Management of TPN-related hepatobiliary dysfunction should start with ruling out other causes such as infection or drug induced liver injury (DILI), seeking consultation with nutritionists to optimize parenteral prescriptions, and advancing to enteral feeding when possible [42].

**Sepsis and Multiorgan System Failure**

The liver often sustains injury and develops dysfunction with sepsis and the systemic inflammatory response syndrome. The injury that occurs in the first hours is most often a consequence of liver hypoperfusion, usually in the setting of shock. This can lead to alterations in liver function including disseminated intravascular coagulation (DIC) and bleeding complications. Progressive liver injury then accompanies systemic effects with the release of bacterial and inflammatory mediators [49]. The liver also contributes to the host immune response through a variety of mechanisms. The portal circulation, which arises from the splanchnic vasculature, is susceptible to vasoconstriction and bacterial translocation during sepsis [50]. The liver is composed of several types of cells, including hepatocytes, Kupffer, endothelial sinusoidal, stellate, NK cells, and others. All these cells contribute to the hepatic response in sepsis through a series of intercellular interactions as well as through circulating or secreted factors. Kupffer cells are responsible for production and clearance of inflammatory mediators, bacterial scavenging, and toxin inactivation [51]. The hepatocytes respond by altering their basic metabolic pathways toward gluconeogenesis and increased production of cytokines and coagulant proteins. Lactate clearance and protein synthesis are reduced. Endothelial cells are responsible for the production of cytokines in response to endotoxins. They further contribute to antimicrobial activity and host defense through production of nitric oxide. Activated neutrophils are also recruited to the liver and respond by release of oxygen-free radicals and destructive enzymes, such as protease...
The acute-phase reactants produced in this setting promote a procoagulant state and induce activation of other cells involved in the immune response. However, the liver can be damaged by cytokines released by Kupffer cells as well as by factors released from activated neutrophils. The subsequent fibrin deposition and hepatocyte damage can adversely affect the microcirculation of the liver, thereby leading to progressive liver damage and systemic toxicity [52]. The role that the liver plays in the immune and metabolic responses to infection can lead to significant clinical sequelae. The majority of patients with bacteremia have abnormal liver tests. Aminotransferase elevation is characteristic in this setting and is reflective of cellular and mitochondrial injury. Abnormal liver enzymes and jaundice can occur 2 to 3 days after the onset of bacteremia. It is common to see liver enzyme elevations reaching two to three times the upper limit of normal. The serum bilirubin level also may reach 5 to 10 times normal in the setting of sepsis [53].

Prompt treatment of sepsis with supportive care and antibiotic therapy can result in normalization of enzymes and reversal of the associated hepatic dysfunction. There is no current evidence to support the use of antibodies directed toward endotoxins or cytokines for management [54]. The use of a stress dose of steroids has been found to favorably affect host defenses and reduce bacterial colonization of the liver during endotoxemia, but its use in sepsis without shock is controversial and does not appear to be beneficial [55,56].

Multisystem organ failure is an ominous sign of progressive critical illness. Hepatic dysfunction in this setting is a poor prognostic indicator. Sepsis, hemorrhage, severe trauma, or tissue injury such as pancreatitis can precipitate this clinical picture. Hepatic hypermetabolism leads to relative systemic hypoperfusion, and multiple organ injury develops because tissue perfusion is continually compromised. In these conditions, the liver reduces protein synthesis, increases protein catabolism, and decreases detoxification potential. Disproportionately high bilirubin levels compared with aminotransferase levels develop among patients with hepatic dysfunction. Patients with elevations in serum bilirubin greater than 8 mg per dL, without the presence of hemolysis or biliary obstruction, have a mortality rate greater than 90% [56]. Prompt reversal of hypotension can greatly reduce hepatic necrosis, bacterial translocation, and impaired Kupffer cell activity seen in patients with shock.
Although DILI is suspected to be a common clinical problem, its true incidence is difficult to determine. This is most likely owing to underdiagnosis and underreporting because the abnormalities range from asymptomatic liver chemistry abnormalities with a small potential impact to life or function to fulminant hepatic failure with high morbidity and mortality. The culprit drug or medication may be difficult to identify especially in the setting of polypharmacy. A thorough medication history obtained from the patient, relatives, friends, caregivers, and pharmacy records is essential to identify the most likely precipitating agent. Factors to be considered when assessing patients with suspected DILI include clinical presentation and timeline of symptoms, timeline of drug ingestion, concurrent liver disease and other potential etiologies of liver injury, concomitant medications, herbal and substance abuse, biochemical pattern of liver injury, histologic findings, and response to rechallenge [14].

Overall, the combined rate of death and need for transplantation is estimated to be approximately 10%. Although the incidence of DILI increases with age and individuals older than 65 were more likely to have a cholestatic pattern, mortality and need for transplantation were similar in patients older than 65 years of age as compared to individuals younger than 65 [57,58]. A DILI network has been established as the first broad registry in the United States to understand and assess this problem [14], and an online database is available at livertox.nih.gov. According to the DILI network (apart from acetaminophen), antimicrobials and herbal and dietary supplements (45.5% and 16%, respectively) are the most common drug classes causing liver damage. The most common antibiotics found related to DILI were amoxicillin–clavulanate, trimethoprim–sulfamethoxazole, isoniazid, and nitrofurantoin [57].

DILI occurs through a multistep process that is initiated through drug injury and subsequent immune-mediated injury culminating in cellular apoptosis or necrosis. Injury develops from the direct effect of the drugs or their metabolites during hepatic detoxification process through cell stress, mitochondrial inhibition, and/or immune activation. Toxic by-products produced by the cytochrome P450 system or through conjugation can alter cell plasma membranes, cellular enzyme activity, or mitochondria. Drugs and their metabolites can also induce a host immune defense response with inflammatory cytokines, complement system activation, and nitric oxide, playing integral roles in the development of hepatocyte damage. In the final step, apoptosis occurs via an adenosine triphosphate (ATP)-dependent pathway, and necrosis occurs as a result of mitochondrial dysfunction and ATP depletion [59,60].

With the inception of the Drug Induced Liver Injury Network, the pace of research in the field has grown exponentially. Although categorization
was historically presented as either intrinsic (dose dependent and predictable) and idiosyncratic (unpredictable), our current understanding has evolved to consider multiple factors including host metabolism, drug exposure, environmental factors, immune responses, hepatic repair, and genetic polymorphisms [60].

DILI can be classified by patterns of injury and/or clinical phenotype. Injury patterns are described as hepatocellular, cholestatic, or mixed hepatocellular-cholestatic based on liver biochemical parameters. Recognizing these patterns can be helpful for narrowing the differential diagnosis, although different patterns can be caused by the same medication (e.g., anabolic steroids causing cholestatic or mixed pattern) [61]. Isolated serum enzyme abnormalities can be simply related to induction of cytochrome P450 enzymes and are not necessarily indicative of hepatotoxicity. Medications such as phenytoin and rifampicin induce the microsomal oxidase systems and can cause elevated γ-glutamyl transpeptidase (GGT) levels. These elevations are usually present in asymptomatic patients and do not represent cholestasis. Drug-induced cholestasis manifests as elevations in serum alkaline phosphatase, total bilirubin, and GGT. Cholestasis can occur with hepatocellular inflammation and necrosis, with associated systemic symptoms such as fever, myalgias, arthropathy, and rash. Toxicity from erythromycin, chlorpromazine, or oral hypoglycemic agents can present with this clinical picture. Cholestasis with minimal or no systemic symptoms can also occur and is the presentation typically associated with anabolic steroid or estrogen use [62]. Because the presentation of drug-induced cholestasis can resemble biliary obstruction, hepatobiliary imaging is often necessary to exclude biliary ductal dilation or a hepatic or pancreatic mass. Complete recovery after cessation of the offending agent may take several months.

Approximately 50% of cases of fulminant hepatic failure are attributed to acetaminophen and 11% are attributed to non-acetaminophen drugs. Continuous and/or repeated exposures to various drugs (such as amiodarone or methotrexate) can also result in chronic liver injury resembling other causes of chronic liver disease, such as autoimmune hepatitis or alcoholic liver disease [59,63]. Drug discontinuation and supportive care remain paramount in the treatment of DILI. Evidence is mixed on specific therapies for DILI, with the exceptions of N-acetylcysteine for acetaminophen toxicity (see Chapter 98) and L-carnitine for valproic acid [64].

**Sinusoidal Obstruction Syndrome**

Sinusoidal obstruction syndrome (SOS), previously referred to as hepatic veno-occlusive disease, is a well-recognized complication of high-dose
chemotherapy and total body irradiation in stem cell transplantation (SCT) recipients [65]. SOS has also been reported in patients who ingested food contaminated with pyrrolizidine alkaloids (bush tea), following liver transplantation (LT), and after long-term use of azathioprine and other chemotherapeutic agents [66,67]. Although the incidence of SOS varies considerably, there is a perception of a declining occurrence owing to newer nonmyeloablative conditioning regimens, avoidance of cyclophosphamide, and better patient selection.

Initially, the syndrome was thought to occur primarily as a result of injury directed toward the hepatic venules, with progressive venular obliteration, hepatocyte necrosis, and fibrosis. More recent studies indicate that venular involvement is not essential to pathogenesis and that sinusoidal obstruction is the primary mechanism behind disease development [68,69]. In SOS, damage to hepatocytes and sinusoidal endothelial cells is a central pathogenic event.

Classically, 3 to 4 weeks after the triggering event, the affected patient develops weight gain (fluid retention and ascites), right upper quadrant pain (tender hepatomegaly), and jaundice. Laboratory abnormalities begin with isolated hyperbilirubinemia (mostly conjugated or direct), followed by elevations in alkaline phosphatase and aminotransferases [70,71]. A high index of clinical suspicion must be maintained for a successful diagnosis because several other conditions have similar presentations. Clinical presentation may be similar to Budd–Chiari syndrome, congestive hepatopathy (i.e., right-sided heart failure, constrictive pericarditis, tricuspid regurgitation, pulmonary hypertension), graft-versus-host disease (GVHD), or a disseminated fungal infection [72,73].

The initial diagnosis of SOS is often made on clinical grounds, but the gold standard for diagnosis is liver histology. The major histologic features are sinusoidal congestion and fibrosis, necrosis of pericentral hepatocytes, narrowing and eventually fibrosis, and obliteration of sublobular and central venules [74]. In early stages, the histologic changes may be patchy, which may lead to erroneous interpretation. A transjugular approach to measure the hepatic venous pressure gradient (>10 mm Hg) may have diagnostic and prognostic implications and facilitates obtaining a liver biopsy. Numerous biochemical markers, including plasminogen activator inhibitor 1 (PAI-1), serum procollagen type III, and antithrombin, have been investigated as diagnostic markers for SOS, but further investigation is needed prior to clinical application [74–76]. Imaging is useful for excluding other causes of liver dysfunction, such as biliary obstruction or malignancy, than in establishing the diagnosis of SOS.
Prognosis depends on the extent of hepatic injury and is classified into three stages: mild, moderate, and severe. The degree and rate of bilirubin elevation appear to be the best biochemical markers of prognosis. Mild to moderate disease is characterized by eventual resolution of liver dysfunction, whereas severe disease is associated with multiorgan failure and a mortality rate approaching 100%. Death is a consequence of renal, pulmonary, or cardiac failure other than liver failure [77].

Current guidelines recommend various preventive strategies after risk assessment. Risk factors include underlying hepatic disease, age, source of stem cells, conditioning regimen, age, sex, and metastatic malignancy. The strongest evidence exists for the use of defibrotide and ursodeoxycholic acid for prophylaxis, whereas agents such as pentoxifylline, prostaglandin E1, heparin, and antithrombin are not recommended because of mixed data and lack of randomized controlled trials [78–80].

Supportive care is paramount to management of SOS in all stages of disease and includes minimizing sodium load, administration of diuretics, and therapeutic paracentesis. Spontaneous resolution has been reported in 70% to 85% of patients in mild cases [71,81]. There is a paucity of evidence for therapeutic interventions for severe SOS, the strongest of which supports the investigational use of defibrotide.

Defibrotide, a single-stranded oligonucleotide with antithrombotic, thrombolytic, and anti-ischemic effects, has been shown to improve survival in recent phase II and phase III trials and is currently available on an investigational basis for severe SOS. Optimal dosage and route of administration have yet to be determined [78,79,82].

Other therapeutic options for SOS such as TIPS, methylprednisolone, and liver transplantation may be considered, but extensive experience is still lacking [80,82].
GRAFT-VERSUS-HOST DISEASE

GVHD is a major cause of morbidity and mortality affecting up to 60% of patients after allogeneic stem cell transplant (SCT) and is thought to be a reaction between the donor’s immune system and the recipient’s tissues [83]. Acute GVHD generally presents before day 100 after transplant and commonly affects the skin, the gastrointestinal tract, and the liver [84]. Chronic GVHD was initially described as occurring after the first 100 days, but recent increases in reduced-intensity conditioning and prophylactic measures have blurred these lines and led to new descriptions of late-onset acute GVHD and overlap syndromes both occurring after 100 days [85]. Discussions within this text will be limited to acute GVHD.

Hepatic involvement of acute GVHD manifests most commonly with elevated bilirubin and alkaline phosphatase with or without hepatitis and rarely occurs without GI or cutaneous manifestations [86,87]. Diagnosis is generally clinical and should be considered in any patient who presents with abdominal pain with diarrhea, classic rash, and/or rising bilirubin within 100 days following transplantation [88]. It is imperative to investigate other causes of hepatic dysfunction, such as sepsis, viral hepatitis, SOS, and drug toxicity. In some cases, a biopsy may be required for histologic confirmation. When hepatic GVHD presents in conjunction with cutaneous and/or GI manifestations, tissue can be obtained from the skin or GI tract. In rare cases of isolated hepatic GVHD, liver biopsy may be needed to confirm the diagnosis. Because many SCT patients present with thrombocytopenia, percutaneous liver biopsy carries significant bleeding risk and a transjugular approach may be preferable.

Grading of disease has prognostic implications and depends on the extent (stage) of dermal, GI, and hepatic involvement as well as performance status. Severe GVHD, grade III and grade IV, carry the worst prognosis with long-term survival being 25% and 5%, respectively, and persistent jaundice is an independent predictor of mortality [89,90].

Prevention and management of GVHD is complex and must be approached in conjunction with a bone marrow transplant center. Treatment of GVHD is nonstandardized and institution specific, but most utilize corticosteroids as first line which is continued for several weeks in responders followed by a slow taper. Patients who do not respond or progress within the first 5 to 7 days are considered steroid refractory and carry a poor prognosis [91]. There is no standard treatment for steroid refractory acute GVHD, but second and third line therapies include mycophenolate mofetil, etanercept, pentostatin, extracorporeal photopheresis, antithymocyte globulin, antitumor necrosis factor-α
antibodies, interleukin-2 antibodies, alemtuzumab, and mesenchymal stem cells. In severe refractory hepatic GVHD, several case reports and series have reported LT as an effective therapeutic option [92].
CHRONIC LIVER DISEASE

Chronic liver disease is a result of continuous, long-term hepatic injury. Chronic viral hepatitis is arbitrarily defined as the presence of persistent liver inflammation, liver chemistry abnormalities, and positive serologic and molecular markers for more than 6 months. The persistent nature of the hepatic insult leads to a sequence of damage and repair processes that may ultimately progress to the development of fibrosis, cirrhosis, and hepatocellular carcinoma (HCC). Damage to the hepatic parenchyma, with or without fibrosis, is a common outcome of chronic liver disease. Regardless of whether the insult to the hepatocytes, the biliary ducts, or the hepatic vasculature is toxic, viral, metabolic, autoimmune, or ischemic, the reparative process often leads to similar outcomes.

Cirrhosis is a chronic diffuse condition characterized by replacement of liver cells by fibrotic tissue, which creates a nodular-appearing distortion of the normal liver architecture. Chronic liver disease and cirrhosis affects nearly 5.5 million Americans; cirrhosis is the 12th leading cause of death in the United States [93], but this mortality figures associated with liver disease may be an underestimation because it failed to capture deaths related to specific conditions of chronic liver diseases such as viral hepatitis and HCC [94].

Etiologies

Chronic hepatitis C virus (HCV) disease, alcoholic liver disease, and nonalcoholic fatty liver disease (NAFLD) are the most common causes of chronic liver disease in the United States. HCV infection is the most common chronic blood-borne infection in the United States, with 30,000 new cases reported in 2013 [95]. Recent estimates of HCV infection at 2.2 to 3.2 million cases did not include incarcerated, homeless persons and persons in active military duty, which were not accounted for by national surveys [96]. Recent guidelines from US national health agencies such as the Center for Disease Control [97] and US Preventative Task Force [98] recommend screening HCV in persons born between 1945 and 1965, the so-called baby boomers owing to high prevalence (75%) of HCV in this population [96]. Highly potent direct acting antivirals with cure rates >90% in most cases are creating a significant impact on patients with chronic hepatitis C [99,100].
Worldwide about 240 million people are chronically infected with the hepatitis B virus (HBV), and more than 780,000 die every year of complications such as cirrhosis and liver cancer [101]. It is the most common cause of liver cancer worldwide; and it is unevenly distributed throughout the world. In endemic areas (East Asia and sub-Saharan Africa), the infection is predominantly vertically transmitted from the mother to the infant. In contrast, in Western countries where HBV is relatively uncommon, the infection is acquired in adulthood. In 2013, there were 20,000 new cases of HBV in the United States with an estimated prevalence of 1.4 million [95], but it may be higher at around 2.2 million if adjusted for foreign-born infected persons [102]. Immigration of persons from endemic countries has contributed to the prevalence of chronic HBV in the United States [103].

Alcoholic liver disease is a significant medical and socioeconomic problem worldwide. Although alcohol exerts a direct toxic effect on the liver, significant liver damage develops among only 10% to 20% of those patients with chronic alcohol abuse. The spectrum of alcoholic liver disease is broad, and a single patient may be affected by more than one of the following conditions: fatty liver, alcoholic hepatitis, or alcoholic cirrhosis (common cause of end-stage liver disease and HCC). Severe alcoholic hepatitis is a form of alcoholic liver disease associated with jaundice and coagulopathy, with a 30% to 50% 1-month mortality [104]. Alcoholic hepatitis–related hospitalization increased from 2002 to 2010, and inpatient mortality decreased during this period [105]. Alcoholic liver disease alone or in combination with other liver-related disease is one of the most common indications for liver transplant in the United States [106].

NALFD and its more severe form nonalcoholic steatohepatitis (NASH), is a clinicopathologic syndrome that encompasses several clinical entities that range from simple steatosis, steatohepatitis, fibrosis, and end-stage liver disease in the absence of significant alcohol consumption. It is now recognized as the most common liver disease in the Western world [107]. The worldwide prevalence of NAFLD is estimated at 20% to 30% in Western countries and 5% to 18% in Asia [108]. A meta-analysis estimated a 24% global prevalence of NAFLD correlated with economic status [109]. It affects both children and adults, and the incidence increases with age. NAFLD is associated with an increasing prevalence of type 2 diabetes, obesity, and metabolic syndrome (including abdominal obesity, dyslipidemia, hypertension, and insulin resistance) in the US population. NALFD-induced cirrhosis may progress to HCC and in the Veteran’s Affairs population; it is the third most common risk factor for HCC [110]. NASH is predicted to become the leading cause of liver and liver–kidney transplantation in the United States by 2020 [101,111].

Other causes of chronic liver disease include autoimmune liver disease,
PSC, PBC, hemochromatosis, Wilson disease, α1-antitrypsin deficiency, and Budd–Chiari syndrome. It is important to recognize acute decompensation in Wilson disease because this condition is universally fatal without a liver transplant.

Clinical Manifestations and Diagnosis

Clinical manifestations of chronic liver disease vary according to the functional and histologic stage of the liver disease. Patients may be asymptomatic or have one or several manifestations of liver dysfunction. Physical findings described in patients with cirrhosis include temporal wasting, jaundice, telangiectasia, gynecomastia, ascites, splenomegaly, caput medusae, palmar erythema, and testicular atrophy. Some laboratory abnormalities are suggestive of cirrhosis. Serum albumin, bilirubin, and PT/INR, which are good indicators of hepatic synthetic function, are frequently abnormal. Thrombocytopenia should raise the suspicion for portal hypertension and cirrhosis. These markers may reflect the degree and progression of chronic liver disease and play an important role in determining patient prognosis.

The severity of chronic liver disease is often scored by the Child–Turcotte–Pugh classification, which considers variables such as serum albumin, serum bilirubin, PT, and the degree of ascites and encephalopathy (Table 206.1). The model for end-stage liver disease (MELD), calculated from the INR, total bilirubin, and creatinine, predicts survival in patients with chronic liver disease awaiting transplant. It was initially envisioned as a tool to evaluate patients undergoing transjugular intrahepatic portosystemic shunt (TIPS); it is now primarily used to prioritize liver allocation for LT in patients with end-stage liver disease [112].

Noninvasive imaging techniques, including ultrasonography, computerized tomography, and magnetic resonance imaging, can identify hepatic steatosis, cirrhosis, and liver cancer but will miss advanced fibrosis and early cirrhosis. There is significant progress in noninvasive fibrosis staging and diagnosis of cirrhosis with the use of serum markers and tools such as elastography. Among the noninvasive techniques, transient elastography is the most validated [113]. Transient elastography that uses the propagation of shear waves to measure liver stiffness is an accepted method of assessing liver fibrosis in patients with HCV by the European guidelines [114]. Transient elastography, as approved by the Food and Drug Administration in 2013, has entered clinical practice in the United States [115]. However, liver biopsy remains the gold standard to establish the severity of liver inflammation and fibrosis.

Complications and Management

The four hallmark complications of cirrhosis are ascites, hepatic encephalopathy, variceal bleeding, and jaundice. The important distinction between compensated cirrhosis and decompensated cirrhosis is the appearance of one of these complications. Hospitalization at diagnosis or at any time with liver disease signals a worse prognosis independent of the cirrhosis stage [116]. Hepatic encephalopathy that ranges from subtle cerebral dysfunction to deep coma is a complication of end-stage liver disease that can result in multiple hospitalizations and decrease life quality. Portal hypertension from cirrhosis has significant consequences. Clinical manifestations of portal hypertension include splenomegaly, esophageal and gastric varices, portal hypertensive gastropathy, colopathy, and ascites. Spontaneous bacterial peritonitis
(SBP) occurs in the setting of ascites, and patients with recent upper GI bleeding or Child–Pugh B/C score with low protein ascites are particularly at risk. Hepatorenal syndrome (HRS), a functional renal dysfunction as a result of severe cirrhosis, is associated with poor prognosis and should prompt an urgent evaluation for liver transplant. Complications of chronic liver disease may result in frequent admissions to the ICU.

**Hepatic Encephalopathy**

Hepatic encephalopathy is a syndrome of disordered consciousness, psychiatric, neurologic, and neuromuscular abnormalities, as a result of chronic liver disease and/or portosystemic shunts [117]. Pathogenesis of this disorder is complex and incompletely understood. In-hospital mortality remains around 15% [118]. Clinical features range in severity from subclinical encephalopathy, manifested by disturbances in psychometric testing to coma (see Chapters 145 and 146). Symptoms may wax and wane over the clinical course of decompensated liver disease. Cerebral edema and elevated intracranial pressure seen with acute liver failure are not present in patients with hepatic encephalopathy and cirrhosis. Serum ammonia is a popular marker for encephalopathy in chronic liver disease. However, there is poor correlation between ammonia levels and clinical disease [119], and, in many cases, results are of uncertain utility [120]. No single test is available to accurately assess the presence or degree of encephalopathy.

Encephalopathy is usually precipitated by an acute event such as increased nitrogen load (GI bleeding, excess dietary protein intake, azotemia, and constipation), the use of certain medications (sedatives, narcotics, and diuretics), infection (SBP, pneumonia, and urinary tract infection), electrolyte abnormalities (hypokalemia and hyponatremia), TIPS, or surgical shunting, or superimposed acute liver disease. Noncompliance to lactulose is a common precipitant. Progression of the underlying liver disease can eventually lead to worsening encephalopathy.

Evaluation of patients with encephalopathy should start with identification of the precipitating event. Metabolic abnormalities such as abnormal serum sodium, potassium, and glucose as well as hypoxemia should be corrected. Hyponatremia is common, and rapid correction may be deleterious. Hypovolemia should be corrected with fluid resuscitation. Infection should be investigated with cultures obtained from urine, blood, sputum, and ascites. Given the coagulopathy associated with chronic liver disease, a lumbar puncture should be pursued only if clinically imperative and after correction of blood clotting abnormalities. The presence of GI bleeding should be investigated. Prior history of medications or toxic
Ingestions should be reviewed.

Medications that decrease endogenous nitrogen production and nitrogen delivery to the liver play an important role in treating encephalopathy. Lactulose is a nonabsorbable disaccharide that reduces the intestinal production and absorption of ammonia [121]. The dose of lactulose should be titrated to achieve three to five soft stools a day, starting at 30 mL orally or via nasogastric tube every 2 to 4 hours. Lactulose can also be given as an enema in patients with an ileus or in those at increased risk of aspiration (300 mL lactulose in 700 mL distilled water). Rifaximin is a nonabsorbable rifamycin antibiotic that should be added to lactulose if symptoms persist; it has been shown to maintain remission from hepatic encephalopathy and reduce hospitalization related to hepatic encephalopathy [122]. Before rifaximin became available, neomycin and metronidazole have been used in addition to lactulose and may be used as an adjunct in resource-limited setting or where rifaximin is not available. However, side effects such as ototoxicity and nephrotoxicity (neomycin) and peripheral neuropathy and dysgeusia (metronidazole) limit their widespread and long-term use. Oral branched chain amino acids improve manifestations of hepatic encephalopathy without any effects on survival [123]. Glycerol phenylbuterate (GPB) which lowers ammonia by an alternative pathway where it is metabolized and excreted in urine may have additional benefits of reducing episodes of hepatic encephalopathy and hospitalization in patients already on rifaximin [124]. Polyethylene glycol (PEG) 3350-electrolyte solution resulting in rapid gut catharsis was shown to lead to more rapid hepatic encephalopathy resolution compared to lactulose, suggesting possible superiority to lactulose which is the standard of care [115]. However, PEG administration would require an enteral tube, rapid administration of a large volume of the solution over a short period of time, and the potential for electrolyte abnormalities and dehydration. More studies are needed on GPB and PEG before these agents can be recommended. Refractory hepatic encephalopathy can occur in 8% of patients with TIPS and can be successfully managed by downsizing the TIPS [125]. Large spontaneous portosystemic shunts may occur in patients with refractory hepatic encephalopathy, and embolization of these shunts may be safe and effective [126].

**Variceal Bleeding**

Portal hypertension is characterized by increased resistance to portal flow and increased portal venous inflow owing to splanchnic dilatation. Portal hypertension is defined by measuring the pressure difference between the hepatic vein and the portal vein (normal pressure gradient 3 mm Hg) through transjugular approach. Clinically significant portal hypertension
is >10 mm Hg and has a prognostic significance \[127\]. Portal pressure gradient >12 mm Hg increases the risk of variceal bleeding \[128,129\]. Portal hypertension induces hemodynamic changes in the hepatic and splanchnic blood flow, with the development of portosystemic collateral circulation (esophagus, stomach, rectum, umbilicus, and retroperitoneum) and splenomegaly. Varices are present in about 50% of patients with cirrhosis \[127\]. Primary prophylaxis is recommended for patients with small varices with red wale signs or in patients with large varices. Unfortunately, at least 10% of patients are intolerant to nonselective β-blockers \[130\]. Bleeding from gastric and esophageal varices is a common indication for ICU admission in patients with cirrhosis. Variceal bleeding presents with hematemesis, melena, or hematochezia. The bleeding event is often dramatic and associated with severe hemodynamic instability and frequently followed by hepatic encephalopathy.

Initial management involves airway protection for active hematemesis or advanced encephalopathy and volume resuscitation. Caution against over transfusion is warranted, with recent evidence showing higher mortality in patients who were liberally transfused (hemoglobin > 9 mg per dL) compared to the patients who were judiciously transfused (hemoglobin > 7 mg per dL) \[131\]. Comprehensive management of patients with GI bleeding related to portal hypertension must include the following considerations: primary prophylaxis (banding of esophageal varices or use of nonselective β-blockers), treatment of the active hemorrhage (blood/volume resuscitation, banding of esophageal varices, octreotide infusion, and antibiotic prophylaxis), and prevention of rebleeding (secondary prophylaxis with nonselective β-blockers). In esophageal bleeding refractory to endoscopic treatment or in the case of bleeding gastric varices, consideration has to be given to salvage therapy with transjugular intrahepatic portosystemic shunt (TIPS) \[127\]. Balloon retrograde transvenous obliteration (BRTO) of gastric varices is an established technique for the management of bleeding varices. This technique was initially used in Japan and Korea but is becoming increasingly available in the United States. There is insufficient data to compare TIPS and BRTO. Additionally, there are no randomized controlled trials on BRTO \[132\].

Coagulopathy with markedly elevated PT, INR, and partial thromboplastin time is common in chronic liver disease. The coagulation profile of a patient with chronic liver disease is significantly different from a normal patient because there are deficiencies in the synthesis of
coagulation factors in both procoagulant and anticoagulant pathways [133]. Transfusion-related lung injury is a dangerous consequence of overtransfusion and can progress to acute lung injury and acute respiratory distress syndrome. Thrombocytopenia is common among patients with splenomegaly secondary to cirrhosis, and it is a consequence of hypersplenism. In our experience, transfusion of platelets should be limited to those patients who are actively bleeding or undergoing an invasive procedure.

Ascites, Hydrothorax, and Hyponatremia

Mechanisms responsible for the formation of ascites are complicated, multifactorial, and result in sodium and water retention. Circulatory dysfunction characterized by arterial vasodilation and low peripheral vascular resistance with hypotension, high cardiac output, and hypervolemia is seen in patients with portal hypertension and ascites. Levels of nitric oxide, a potent vasodilator, are elevated in the splanchnic circulation of patients with ascites. The ensuing arterial vasodilation triggers activation of baroreceptor-mediated systems, the renin–angiotensin–aldosterone system, and the sympathetic nervous system, inducing sodium retention. Regulation of water balance is also disrupted in patients with cirrhosis. As a result of the reduced effective intravascular volume, arginine vasopressin levels are elevated. The major clinical consequence of this elevation is dilutional hyponatremia, which occurs despite an avid sodium state [134].

Patients with large volume ascites present with abdominal distension with a fluid wave or shifting dullness on examination. Respiratory compromise from associated pleural effusion (hepatic hydrothorax) or increase intra-abdominal pressure may result. Large volume ascites may also induce the development of ventral and umbilical hernias, with increased risk of intestinal strangulation or hernia rupture.

Analysis of the ascitic fluid is essential for the appropriate management of patients with decompensated liver disease. Small volume (60 mL) diagnostic paracentesis should be performed in patients hospitalized with ascites. Even in the presence of severe coagulopathy, it is safe to remove fluid [135]. Infection and bleeding are rare complications (<1%) [136]. The ascitic fluid should be sent for cell count and differential, culture, albumin, and total protein. Additional tests such as triglycerides (chylous ascites), amylase (pancreatic ascites), adenosine deaminase (peritoneal tuberculosis), and cytology (malignant ascites) should only be sent as clinically indicated. An SAAG more than 1.1 g per dL indicates portal hypertension with 97% specificity. An SAAG less than 1.1 g per dL is found in nephrotic syndrome, peritoneal carcinomatosis, serositis, tuberculosis, and biliary and pancreatic ascites. Ascitic fluid total protein
is helpful and expectedly low (<2.5 g per L) in portal hypertension. A high SAAG, high-protein ascitic fluid should prompt evaluation for posthepatic etiologies such as heart failure and constrictive pericarditis. Restriction of sodium intake to 2,000 mg per day and minimizing intravenous (IV) sodium load (fluids, antibiotics, TPN, and blood transfusions) play an important therapeutic role.

Most patients will require combination of a potassium-sparing diuretic and a loop diuretic to achieve a more rapid natriuresis and to maintain normal potassium levels. Starting dose of spironolactone is 100 mg daily and furosemide 40 mg daily. Titration every 3 to 5 days (maintaining a 5 to 2 mg ratio) to maximum daily doses of 400 mg of spironolactone and 160 mg of furosemide is the recommended approach [137]. About 10% of patients will fail diuretic therapy and develop refractory ascites. LVP can safely remove 8 to 10 L as a therapeutic measure for patients with tense ascites. The administration of albumin (6 to 8 g per L of ascites removed) during LVP has been associated with a lower incidence of hemodynamic disturbances without affecting survival [138,139]. Refractory ascites is a condition that develops in patients who do not respond adequately to maximum doses of diuretics. Progressive intravascular volume depletion, renal failure, and electrolyte abnormalities may limit the use of high-dose diuretics. Among these patients, the use of angiotensin converting enzyme inhibitor (ACEI) and angiotensin receptor blockers (ARBs) should be avoided. Nonselective β-blocker should be discontinued if there is systemic hypotension. A reasonable alternative in patients with refractory ascites requiring frequent LVPs with preserved liver function is TIPS. Complications associated with TIPS include hepatic encephalopathy, cardiopulmonary compromise, pulmonary edema, transient pulmonary hypertension, infection, bleeding, ischemic hepatitis, and shunt occlusion. Peritoneovenous shunt may be considered for patients who are not TIPS candidate as a palliative measure; unfortunately, occlusion and infection are frequently associated complications that limit their generalized use. Patients with cirrhosis and ascites should be considered for LT. An expedited referral for patients with refractory ascites is recommended [137].

Hepatic hydrothorax is a transudative pleural effusion of patients with portal hypertension in the absence of an underlying cardiopulmonary or pleural process. It occurs in 5% to 10% of cases. Although frequently occurring in the right pleural space caused by direct passage of peritoneal fluids through diaphragmatic defects, left-sided and bilateral hydrothorax occur 13% and 2% of the time, respectively [140]. The medical management is similar to that of ascites with dietary sodium restriction and diuretics. Some of these patients will be considered refractory, and regular thoracentesis will be necessary to alleviate symptoms. Consideration for TIPS in patients with low MELD is a reasonable
alternative to regular thoracentesis. A small collection of noncontrolled trials of 198 patients who underwent TIPS reported response rates (both complete and partial) ranging from 59% to 82% is reported [141]. Among selected patients with severe liver disease wherein placement of a TIPS is potentially hazardous such as in cases with MELD score >15, there are some reports of success with implantation of indwelling pleural catheters [142].

Spontaneous bacterial empyema (SBEM) is an important and underdiagnosed complication of hydrothorax, with an observed mortality of 20% to 35% [143]. The name is misleading because there is no pus in the thoracic cavity; and the etiology, pathogenesis, and treatment are different from empyema. The diagnosis is established after pneumonia or parapneumonic effusion is excluded on imaging by pleural fluid analysis showing either (1) a neutrophil count > 250 cells per μL and a positive pleural fluid culture or (2) >500 neutrophils per μL in the absence of a positive culture [144,145]. The typical organisms mirror that of SBP [143]. Treatment with a third-generation cephalosporin for 7 to 10 days is recommended. The concurrent treatment with albumin, as practiced in spontaneous bacterial peritonitis, has not been studied in SBEM. Chest tube placement should be avoided because it is associated with infection, high output, dehydration, and increased mortality [146].

With cirrhosis, hyponatremia develops in the setting of ascites in a state of avid renal sodium retention and increased extracellular fluid volume (hypervolemic hyponatremia) or from excessive losses of sodium and extracellular fluid (hypovolemic hyponatremia). Hyponatremia correlates with the severity of liver disease and is associated with poor outcomes [147]. The patient’s volume status determines the treatment. Volume expansion is necessary for hypovolemic hyponatremia. Hypervolemic hyponatremia is common in cirrhosis and is usually tolerated, so rapid correction (>8 mmol per L in a day) should be avoided because of neurologic complications of osmotic demyelination syndrome. There is a lack of data on when treatment for hyponatremia should be initiated. In general, fluid restriction to 1 L per day is recommended for patients with serum sodium <125 mEq per L. Hypertonic saline is only recommended if hyponatremia is associated with neurologic symptoms because of associated problems with infusion [137]. Vaptans are vasopressin receptor 2 antagonists that block the action of arginine vasopressin in the distal tubule of the kidneys. These agents result in solute-free diuresis and have been used in patients with cirrhosis, dilutional hyponatremia, and ascites. There are two approved agents in
the United States. Conivaptan is a combined V1a- and V2 receptor antagonist that carries the theoretical risk of hypotension, variceal bleeding, and worsening kidney function. The other approved agent is tolvaptan. A previous long-term study on tolvaptan for the treatment of hyponatremia showed that tolvaptan is safe, resulting in a modest response among cirrhotics with no liver injury reported [148]. However, after a randomized controlled trial that used tolvaptan in adult polycystic kidney disease to inhibit cyst growth and preserve kidney function showed high discontinuation rates owing to hepatic adverse events [149], tolvaptan is no longer approved by the Food and Drug Administration for patients with cirrhosis because of a reported higher frequency of elevation of liver enzymes. It is important to note that the doses used in this trial in adult polycystic kidney disease were much higher than in the previous studies of cirrhosis [150]. In our experience, small doses of vaptans over a short period of time were generally safe, but the small improvement in hyponatremia vanished with discontinuation of the vaptans. A meta-analysis of 12 trials on the safety and efficacy of vaptans showed small benefit in hyponatremia and ascites with no beneficial effect on mortality [151]. Thus, the routine use of vaptans is not recommended [137], but there may be a role in the short-term use of tolvaptan in patients awaiting LT [147].

**Spontaneous Bacterial Peritonitis**

SBP is an infectious complication resulting from intestinal bacterial translocation that occurs through altered gut permeability and bacterial overgrowth. The intestinal microbiome and genetic and acquired immune defects are linked to the development of infection [152]. SBP develops in the setting of reticuloendothelial system depression and leukocyte dysfunction along with decreased opsonic activity in the ascitic fluid [153,154]. Twelve percent of patients with ascites admitted to the hospital for any reason have SBP, and it is associated with high in-hospital mortality (16% to 23%) [155]. Acute kidney injury (AKI) often complicates SBP and prevention of AKI is associated with reduced mortality [156].

A polymorphonuclear cell count of more than 250 per μL or the presence of a positive bacterial culture in the ascitic fluid establishes the diagnosis of SBP. Inoculation of culture bottles at bedside improves bacterial culture yield [157]. Identification of more than one organism raises the possibility of secondary bacterial peritonitis usually related to another intra-abdominal process. The most common organisms responsible for SBP are the gram-negative enteric bacteria, *Escherichia coli*, *Klebsiella pneumoniae*, and *Streptococcus pneumoniae* [157]. Because the identification of organisms is not immediately available,
treatment should be targeted at the most likely culprits. The ideal antibiotic should have both gram-negative and enteric organism coverage without nephrotoxicity. A third- or fourth-generation cephalosporin (cefotaxime and ceftriaxone) and ampicillin/sulbactam are the recommended first-line agents. Repeat paracentesis should be performed in patients who are not responding to therapy after 48 hours. If a 50% decrease in polymorphonuclear cell count is not seen after 72 hours of antibiotic use, antibiotic coverage should be broadened. Antibiotics resistance is increasingly recognized [158], and failure of first-line treatment caused by increasing rates of bacterial resistance is associated with poor prognosis [159]. Nosocomial SBP is very problematic because it is often caused by multidrug-resistant bacteria. Piperacillin/tazobactam or meropenem with and without a glycopeptide is the recommended approach in Europe for nosocomial SBP [158]. A randomized trial showed superior outcomes in nosocomial SBP treated empirically with meropenem and daptomycin compared to ceftazidime (a third generation cephalosporin) [160].

Administration of IV albumin in addition to antibiotics in the setting of SBP results in a lower incidence of renal impairment, improving short-term survival [161,162]. Owing to the high recurrence rate of infection (70%) [163], prophylactic long-term oral antibiotic therapy is recommended after recovery. Secondary prophylaxis can be achieved with daily norfloxacin, ciprofloxacin, or trimethoprim/sulfamethoxazole. Daily dosing is the preferred frequency to avoid the emergence of antibiotic-resistant strains [157]. Primary antibiotic prophylaxis for SBP is indicated in the setting of acute GI bleeding [164], patients with ascitic fluid protein <1.5 g per dL, more advanced cirrhosis (Child B or C), jaundice (bilirubin > 3 mg per dL), and renal impairment (creatinine 1.2 mg per dL, blood urea nitrogen 25, serum sodium 130 mmol per L) [157,158]. Nonselective β-blocker use after an episode of SBP may be associated with increased hospitalization, hepatorenal syndrome, and mortality by exacerbating hemodynamic compromise in patients with already low systolic arterial pressures (<100 mm Hg) [165]. Finally, the association of the development of SBP with proton pump inhibitor (PPI) use should prompt discontinuation of the PPI in patients who do not have a clear indication [166,167].

Hepatorenal Syndrome

HRS develops during the terminal stages of liver failure as a result of intense splanchnic vasodilatation leading to intravascular hypovolemia and severe renal hypoperfusion. It is a feared consequence of end-stage liver disease and is seen in up to 10% of patients hospitalized with cirrhosis and ascites [168]. In HRS, functional renal failure occurs in the
absence of obvious abnormalities in kidney structure. Conceptually, the kidneys are structurally normal, and the syndrome is reversible with LT in majority of the patients. The primary mechanism in the pathogenesis of HRS involves intense renal vasoconstriction in response to activation of neurohumoral factors including the renin–angiotensin–aldosterone system and the sympathetic nervous system leading to low renal perfusion and glomerular filtration rate [169].

HRS is a form of AKI. An increase in serum creatinine to 1.5 mg per dL had been the threshold to diagnose AKI in cirrhosis [170]. This creatinine cutoff is problematic in patients with sarcopenia or diminished muscle mass and may not reflect the glomerular filtration rate. In addition, the initial small increase in serum creatinine corresponds to a dramatic drop in glomerular filtration rate. The most recent definition of HRS by the International Ascites Club recognized the diagnostic challenges of AKI in cirrhosis. HRS can now be diagnosed in patients with ascites who meet the criteria given in Table 206.2, where the first stage of AKI is defined as an increase in serum creatinine >0.3 mg per dL within 48 hours or a >50% increase in serum creatinine from a known baseline or presumed to have occurred within the prior 7 days [171].

Patients who fulfill this criteria may still have structural damage such as tubular damage.

AKI, acute kidney injury; HRS, hepatorenal syndrome; ICA, International Club of Ascites; sCr, serum creatinine.

There are two clinically distinct types in HRS. Type I HRS progresses rapidly and has a close temporal association with a precipitating event that results in progressive loss of kidney function in 2 weeks. Type II HRS progresses in a slower but relentless fashion as a form of expression of circulatory dysfunction and clinically manifests as diuretic-resistant ascites. In contrast to patients with type II HRS that present with better preserved liver function, patients with type I HRS have a very poor prognosis. They are usually severely ill with marked edema, ascites, sodium retention, hyponatremia, and hypotension. In both cases, the presence of ascites is necessary to make the diagnosis of HRS.

Precipitants of HRS include SBP, infection, large volume paracentesis without plasma expansion, and GI bleeding.

Although diagnostic criteria for HRS have been established (Table 206.2), the distinction between type I HRS and prerenal azotemia may be extremely difficult. In recent studies, both biomarkers, urinary neutrophil gelatinase–associated lipocalin and interleukin-18, have shown the ability to distinguish hepatorenal syndrome from prerenal azotemia and acute tubular necrosis. However, HRS may not be always an entirely functional condition; it may also involve some degree of parenchymal injury which will limit the utility of these biomarkers where there is an overlap [172]. Pharmacologic therapy with splanchnic vasoconstrictor drugs and IV albumin are usually initiated when HRS is suspected. Splanchnic vasoconstrictors used in the treatment of HRS include terlipressin, norepinephrine, or octreotide in combination with the α-agonist midodrine. Among the vasoconstrictors, terlipressin is the most extensively studied but is not available in the United States. Combination
of midodrine (15 mg three times a day), octreotide (200 µg subcutaneously three times a day), and albumin infusion had shown benefit in small studies; this regimen can be given outside the ICU [137]. Terlipressin with albumin has been shown to be more effective than midodrine, octreotide, and albumin [173]. Norepinephrine is a reasonable alternative to terlipressin as it has been shown equivalent with less adverse events [174]. Renal replacement therapy (RRT) is usually required in a majority of these patients as a bridge to LT.

HRS may occasionally be prevented by timely administration of albumin and antibiotics in the treatment of SBP [175]. There had been reports of TIPS as a treatment of types I and II HRS with some success [176–179]; however, the risk of mortality is high because these patients usually have high MELD scores and so TIPS cannot always be advocated. Routine use of RRT may not be beneficial for patients with type 1 HRS already receiving combination treatment of vasoconstrictor plus albumin [180]. Urgent referral for LT is recommended once HRS is suspected. In type I HRS, LT offers better survival. Among patients who do not receive LT, RRT does not provide an improved survival benefit [181]. Although LT is the only curative option, reversal was only seen in 76% of cases of HRS type 1. Duration of pretransplant dialysis was the only observed predictor of reversibility [182].

Hepatopulmonary Syndrome and Portopulmonary Hypertension

Hepatopulmonary syndrome (HPS) is a clinical disorder of impaired oxygenation caused by intrapulmonary vascular dilatation in the setting of portal hypertension and absence of primary cardiopulmonary disease [183]. The clinical features platypnea (shortness of breath improved when supine) and orthodeoxia (fall in the arterial PO$_2$ in the upright position) are unique to this syndrome. Isolated hypoxia should be further investigated with contrast-enhanced echocardiogram or a transthoracic echocardiogram with agitated saline (bubble study). The presence of delayed microbubbles in addition to PaO$_2$ < 80 mm Hg with an A-a gradient is consistent with HPS [184]. HPS is associated with significant increased risk of death and worse quality of life [185,186]. There is no approved therapy, and LT is the only curative treatment. For this reason, MELD exception points are allocated to patients with HPS with PaO$_2$ < 60 mm Hg to facilitate transplantation. Poor outcomes are seen in patients transplanted with PaO$_2$ < 50 mm Hg [185,187].

Portopulmonary hypertension is pulmonary hypertension (pulmonary artery pressure > 25 mm Hg and pulmonary vascular resistance > 240 dynes/s/cm$^5$) in the setting of portal hypertension and absence of other
primary lung disease [188]. Typical symptoms are dyspnea or nonspecific chest discomfort. Diagnosis usually starts with transthoracic echocardiogram where right ventricle systolic pressure is >40 mm Hg and pulmonary artery pressure is >25 mm Hg. Other etiologies of pulmonary hypertension should be investigated and excluded. A right heart catheterization is required to confirm pulmonary artery pressure and resistance and exclude volume overload or left heart failure. Portopulmonary hypertension is associated with significant morbidity and mortality with an estimated 1-year survival without treatment of 60% [184]. MELD exception points are given to patients with pulmonary artery pressure >35 mm Hg. Medical treatment for portopulmonary hypertension is similar to that of pulmonary hypertension. LT, although still offered, may not confer a significant survival advantage [189].

Liver Transplantation

LT can be lifesaving in patients with end-stage liver disease. The 1-year survival rate for LT in the setting of chronic liver disease is currently 85% to 90% [190]. With increasing numbers of patients listed for transplantation and the relatively static number of cadaveric organs available, death is not uncommon while awaiting an organ offer. Medical contraindications to LT include uncontrolled sepsis, advanced cardiac or pulmonary disease, multiorgan failure, and advanced malignancies. Psychosocial factors are just as important in transplant listing, and these include unresolved alcoholism, drug addiction, uncontrolled psychiatric disease, compliance issues, and lack of social support or medical insurance coverage. Transplant evaluation should be initiated when there is decompensated liver disease as manifested by the syndromes described in this chapter. In addition, transplant evaluation involves recognizing those patients who are too sick and will not benefit from transplantation. Identification of these patients becomes more difficult because the regional organ allocation for liver prioritizes the sickest patient or the highest MELD score in the list. MELD is an accurate predictor of short-term survival (3 months) in patients with cirrhosis awaiting LT [112,191]. It is a poor predictor of survival posttransplantation [192]. Currently, there are no widely utilized criteria that will accurately predict whether a critically ill patient will survive transplantation.

INTRODUCTION

Acute liver failure (ALF) is a sudden catastrophic deterioration in liver function over a short period of time usually in the absence of preexisting liver disease. The defining feature of ALF is the presence of alterations both in mentation and in coagulopathy. A number of terms have been used for this condition, including fulminant hepatic failure (FHF) and fulminant hepatitis. ALF is the preferred umbrella term [1]. ALF is an uncommon entity, estimated to affect approximately 2,000 to 3,000 patients annually in the United States [2]. Prompt evaluation and aggressive management, including possible liver transplantation (LT), play an integral part in successfully treating patients with ALF in the intensive care unit (ICU). Acute-on-chronic liver failure (ACLF) is the deterioration of liver function in a patient who already has chronic liver dysfunction. It represents a newly recognized, but important, aspect of liver dysfunction among ICU patients. The definition, etiology, clinical features, complications, and management of ALF and ACLF are reviewed in this chapter.
ACUTE LIVER FAILURE

Definition

ALF is an uncommon condition that includes evidence of coagulation abnormalities (international normalized ratio [INR] >1.5) and mental alterations (encephalopathy) of a patient without preexisting cirrhosis and <26 weeks of illness duration [1]. Acute Wilson disease and acute autoimmune hepatitis, when diagnosed within the last 6 months, are widely accepted exceptions that are treated as ALF because of poor outcomes without LT. FHF, although used interchangeably with ALF, has a strict definition when applied to patients under evaluation for LT and is discussed later on in this chapter.

Etiologies

Numerous causes of ALF are recognized, and their relative importance differs around the world. In the United States, acetaminophen accounts for nearly 40% of cases followed by unknown causes (18%) and idiosyncratic drug reactions (13%) [3,4] (see Table 207.1). Acute viral hepatitis has become an infrequent cause of ALF over the last few decades because of effective immunization programs; but in the developing world, it remains the dominant etiology of ALF [5]. The identification of the cause of ALF is important because it can provide prognostic information as well as dictate treatments. Initial laboratory testing to delineate etiology and assess degree of injury is obligatory (Table 207.2). The etiology of ALF may also have prognostic significance in determining outcomes in patients listed for LT [6].

Liver chemistry panel: aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, total and direct bilirubin, albumin, total protein.

Hepatitis B markers: hepatitis B surface antigen, hepatitis B surface antibody, hepatitis B core antibodies (IgG and IgM).

FHF, fulminant hepatic failure; HSV PCR, Herpes simplex virus polymerase chain reaction; HIV, human immunodeficiency virus; CXR, chest X-ray; ECG, electrocardiogram; RUQ US, right upper quadrant ultrasound.
Acetaminophen

Acetaminophen is the most common cause of ALF in the United States and the United Kingdom. This drug is a constituent of numerous over-the-counter preparations and is also commonly combined with prescription analgesics. Although the recommended doses of acetaminophen (up to 4 g per day) are safe in healthy individuals, dose-dependent hepatotoxicity can occur. Hepatotoxicity occurs through intentional or unintentional overdose. Approximately one-third to one-half of cases occur because of efforts at pain relief; these “therapeutic misadventures” occur with lower cumulative doses of ingested acetaminophen, but often times co-ingestion of multiple acetaminophen containing preparations has taken place [7]. These patients may seek late medical attention resulting in delayed physician recognition and worse patient outcomes.

Acetaminophen is 95% eliminated by hepatic conjugation. Approximately 5% of acetaminophen is converted to N-acetyl-p-benzoquinone imine (NAPQI), which is inactivated after reaction with cellular glutathione and excreted rapidly. The glutathione stores become progressively depleted in the setting of acetaminophen overdose because the liver produces more NAPQI. When unable to be excreted, NAPQI becomes highly toxic and produces massive liver necrosis. NAPQI accumulates at a higher rate in the setting of increased cytochrome PCY2E1 activity, as seen with chronic alcohol ingestion, and with medications that induce the P450 system.

Patients with acetaminophen toxicity present in three phases [8]. The first phase involves acute gastrointestinal (GI) symptoms of nausea, vomiting, and abdominal pain within the first few hours after ingestion and aspartate aminotransferase (AST) and alanine aminotransferase (ALT) may begin to rise as early as 8 hours after a massive dose. During the second phase (24 to 72 hours), asymptomatic liver test abnormalities typically occur, with marked elevation of liver enzymes and a high AST to ALT ratio. In severe cases, tender hepatomegaly, jaundice and prolonged prothrombin time may be seen. Nephrotoxicity may also become evident. The third phase (72 to 96 hours) presents with manifestations of hepatic failure, including jaundice and encephalopathy. The mortality of acetaminophen toxicity is higher when associated with severe acidosis, coagulopathy, renal failure, mental status changes, and cerebral edema (CE) [9]. These markers are useful to determine when a patient should be considered for LT.

The effective antidote, N-acetylcysteine (NAC), is potentially lifesaving especially when administered within 24 hours of ingestion. Thus, suspicion and early identification of acetaminophen toxicity are of vital importance in treating patients presenting with ALF. Although the
therapeutic benefit of NAC is best when given within 10 hours, its effects can still be of value within 72 hours of ingestion [10]. When administered early, NAC leads to greater than 95% survival.

NAC replenishes glutathione stores, preventing depletion and subsequent tissue hypoxia and ischemic damage. Both the oral and intravenous (IV) forms can be used with similar efficacy [8]. Oral NAC is given over 72 hours with a loading dose of 140 mg per kg and subsequent doses of 70 mg per kg every 4 hours for a total of 17 doses. It is not uncommon for oral NAC to induce nausea and vomiting, necessitating nasogastric or nasoduodenal feeding tube placement for administration. If the patient develops significant nausea or vomiting, and has a polysubstance overdose requiring gastric decontamination, GI bleeding, or intestinal obstruction, IV NAC is the preferable administration route. IV NAC is given as a 150 mg per kg loading dose, then 50 mg per kg over 4 hours, followed by 100 mg per kg over 16 hours. However, many practitioners extend NAC treatment until there is improvement in liver chemistry parameters. This extended dosing of NAC is seen most often in severe cases of ALF because the benefits often outweigh any adverse effects from the medication. Anaphylactoid reactions are seen in 10% to 20% of patients, typically occurring after the IV loading dose [8]. Because this reaction may be rate dependent, the loading dose has to be administered over 15 to 60 minutes.

**Non-Acetaminophen Drugs**

Non-acetaminophen agents are second to acetaminophen in known causes of ALF. This group largely comprises antibiotics, antiepileptics, and nonsteroidal anti-inflammatory drugs (NSAIDs). Multiple other agents have also been implicated, including neuropsychiatrics, cardioprotectives, chemotherapy, and immunosuppressives, but a complete list is too expansive and beyond the scope of this chapter. Up to 10% of cases may be because of more than one medication [11]. The presentation is often idiosyncratic and may present with a cholestatic, hepatocellular, or mixed pattern of liver enzyme elevations.

Initial management includes prompt identification and cessation of the offending agent. Further management guidelines are variable because this group comprises a wide range of medications and clinical scenarios. NAC is one therapy that has been tried in these patients. NAC was reported to improve transplant-free survival in non-acetaminophen ALF when given in the early stages, that is, before progression to advanced or severe encephalopathy [12]. Analyses of the available data do not demonstrate an overall mortality benefit for patients who received NAC, but mortality benefit was seen in transplant-free survival and posttransplant survival [13]. Overall, NAC can be safely used and may be
advocated while awaiting transplantation or even when transplantation is not an option [14].

Hepatotrophic Viruses

The recognized hepatotrophic viruses are hepatitis A, B, C, D, and E. Although relatively rare in the United States and United Kingdom, fulminant viral hepatitis is the leading cause of ALF in developing countries.

Hepatitis A is typically a self-limiting infection, causing ALF in less than 1% of cases in nonendemic areas. The clinical patterns and manifestations may depend on the age of the host: (1) asymptomatic without jaundice, (2) jaundice and self-limiting symptoms for 8 weeks, (3) prolonged jaundice lasting for more than 10 weeks, (4) relapsing cholestasis or jaundice occurring over 6 to 10 weeks, and (5) fulminant hepatitis [15]. Neither cholestatic nor relapsing variant is associated with increased mortality. Fulminant hepatitis leading to ALF manifest in the first week in over 50% of patients and during the first 4 weeks in 90% [16]. The US Acute Liver Failure Study group identified four predictors (creatinine > 2.0 mg per dL on day 1, ALT > 2,600 IU per mL, intubation, and need for pressor support), which in a prognostic model performed better than the King’s College criteria and model for end-stage liver disease (MELD) scores [17]. Independently, creatinine > 2 mg per dL still had the best sensitivity and specificity for predicting ALF and mortality [18].

Hepatitis B can cause ALF through acute infection or reactivation. Acute infection causes hepatic damage through immune-mediated lysis of infected hepatocytes. Reactivation typically occurs in the setting of immunosuppression and is generally more severe than acute infection with a higher propensity for ALF and death. Nucleoside/nucleotide analogues are the mainstay of treatment and were found safe and efficacious in reducing short-term mortality in acute on chronic liver failure patients [19]. However, these medications may have no benefit in transplant-free survival in ALF because of the rapid disease progression and short duration of treatment [20]. Nevertheless, nucleoside/nucleotide analogues should still be used because these prevent viral recurrence after transplant.

Hepatitis E virus (HEV) usually causes acute, self-limited infection and most often occur in developing countries. However, two distinct epidemiologic patterns of infection are now observed: (1) acute hepatitis via fecal–oral route in endemic areas or developing countries and (2)
chronic hepatitis through ingestion of contaminated meat (zoonotic reservoirs) with rapidly progressive cirrhosis in nonendemic areas or developed countries usually of immunosuppressed patients or recipients of organ transplants. HEV infection can be made by detecting serum immunoglobulin (IgM) (may last up to 4 to 5 months) and IgG antibodies to HEV or HEV ribonucleic acid in stool and serum (not commercially available). The presence of IgM anti-HEV strongly suggests acute infection [21]. Clinical course of HEV infection among pregnant women is known to be more severe and often lead to FHF and death in up to 20% to 25%, specifically among those living in developing countries [22].

Hepatitis C, well known for its role in chronic hepatic failure, is a rare cause of ALF [23].

Non-Hepatotrophic Viruses

Herpes simplex virus (HSV) is a rare cause of ALF, but when untreated is associated with a mortality of up to 90%. It is more likely to occur in immunosuppressed or pregnant patients. Liver biopsy is the gold standard for diagnosis, but serum HSV polymerase chain reaction has both a high sensitivity and specificity [24]. Practitioners should have a high index of suspicion because patients may present without mucocutaneous lesions in up to 30% of cases and prompt initiation of acyclovir improves transplant-free survival [10,25].

Epstein–Barr Virus (EBV) is another important but exceedingly rare cause of ALF, accounting for a mere 0.2% of cases. Consistent with its more common disease, infectious mononucleosis, it is mostly seen in young patients [26]. Diagnosis is difficult to make; but if available, monospot testing, EBV serologies, and EBV DNA testing of serum or liver tissue can be useful. There are no current treatment guidelines, but anecdotal evidence suggests antivirals and corticosteroids may be of benefit [26].

Cytomegalovirus (CMV) infection should also be considered in those with ALF. Diagnosis is confirmed by CMV DNA, anti-CMV IgM antibody, or fourfold increase in anti-CMV IgG antibodies [27]. Ganciclovir is the treatment of choice.

Pregnancy

ALF in pregnancy can be divided into acute fatty liver of pregnancy (AFLP) and hypertension-related liver diseases (preeclampsia, hemolysis/elevated liver enzymes/low platelet [HELLP] syndrome). Quick delivery of the fetus can be both lifesaving for the mother and child for both AFLP and HELLP syndrome. Acute hepatic rupture occurs in about 1% of patients with HELLP syndrome with marked mortality risks to the fetus and mother, in addition to inherent risks of ALF in the
mother [28]. AFLP is a rare condition caused by microvesicular fatty infiltration of the hepatocytes owing to defects in the long-chain 3-hydroxyacyl coenzyme A dehydrogenase (LCHAD) in the fetal mitochondria. This occurs in the third trimester or within a few days postpartum and is associated with high fetal and maternal mortality [29]. Markers to help identify women at risk of death or LT include elevated lactate despite adequate resuscitation and encephalopathy [30].

**Autoimmune Hepatitis**

Autoimmune hepatitis can cause ALF in the setting of newly developed disease, exacerbation of chronic disease, or superimposed injury on chronic disease. The histologic features, elevated autoantibodies, and γ-globulins typical of chronic disease may be variably seen in this setting [31]. Current recommendations advise a trial of corticosteroids because this may prevent the need for LT in some patients [32]. Immediate listing for LT may be appropriate in those with ALF because improvement with corticosteroids alone is unsuccessful in 60% of the cases.

**Unusual Etiologies**

There are multiple rare and important etiologies of ALF. One such entity is *Amanita phalloides* or mushroom poisoning. An accurate history of mushroom ingestion is crucial to recognize and treat this disease. Treatment with gastric lavage or activated charcoal administration is controversial because no evidence exists that this improves clinical outcomes. However, it is a typical practice if patients present early after ingestion. Sylimarin, at a dose of 20 to 50 mg/kg/h IV, is recommended for patients who present within 48 hours of ingestion because this has been shown to prevent amanitin uptake into hepatocytes [33]. Penicillin G also prevents amanitin uptake by hepatocytes by displacing it from binding plasma protein. NAC has also been proposed as a treatment strategy in these patients, although data is limited [33]. Mortality from *A. phalloides* poisoning ranges from 10% to 20%.

Another rare but important entity of ALF is Wilson disease. It comprises 3% of those presenting with ALF and can have a mortality up to 95% [34]. Diagnosing Wilson disease as the cause for ALF can be a challenge because serum ceruloplasmin may be falsely elevated because of this acute inflammatory state. Associated clinical data that suggest Wilson disease include Coomb negative hemolytic anemia, coagulopathy
that cannot be corrected with vitamin K, modest elevations in aminotransferases, elevated serum copper, and elevated 24-hour urine copper [34]. Treatment of these patients is ultimately LT; however, it is important to note that other sequelae of Wilson disease (i.e., neurologic disease) may not improve after transplantation.

Budd–Chiari syndrome is an important cause of ALF. In mild forms of liver injury, treatment with anticoagulation and diuretics may be of benefit, but in patients who present with ALF, LT is the ultimate therapy [35]. Transjugular intrahepatic portosystemic shunts can be used as a bridge to transplant for some patients.

Case reports have also implicated malignancy as a rare cause of ALF. The majority of these cases are secondary to lymphoma and breast cancer [36]. Mortality in this group is high, and LT is contraindicated.
SYSTEMIC MANIFESTATIONS AND MANAGEMENT

Despite timely intervention, multisystem organ failure can develop among patients with ALF. Hepatic encephalopathy (HE) is the defining clinical feature of ALF, and the development of Cerebral edema (CE) presents a unique set of challenges. Cardiorespiratory failure, renal failure, and infectious complications require aggressive management best done by a multidisciplinary team approach. Supportive management is crucial until the liver recovers or is replaced by transplant. Owing to the rare nature of ALF, evidence-based approaches often rely on analysis of retrospective data from a prospective database such as the US Acute Liver Failure Study group.

Hepatic Encephalopathy

HE is a spectrum of neurologic or psychiatric abnormalities resulting from liver insufficiency and/or portosystemic shunting. It is differentiated into three subtypes according to the underlying diseases: ALF, portosystemic shunting, and cirrhosis. HE from ALF is distinguished from the other two causes by its association with CE with increased intracranial pressure (ICP) and risk of cerebral herniation. The presence of HE is required to establish the diagnosis of ALF. Bedside assessment often relies on clinical assessment scores (Table 207.3), which grade HE from minimal changes in behavior (grade 1) to coma (grade 4). Grades 1 and 2 have mild to moderate confusion with or without asterixis. Grade 3 patients are markedly confused and hypersomnolent but arousable. Grade 4 is defined by a comatose state. Distinguishing patients with low grade (grades 1 and 2) from high grade (grades 3 and 4), HE is important in the early management and triage of patients with ALF. Immediate transfer to a transplant center is recommended when the earliest symptoms of HE are recognized in a patient with acute liver injury. The severity of HE may predict the outcome. Three-week survival without transplantation is 33% and 56% in grades 3 and 4 HE.

</tbody>
</table>
Patients with early or low-grade HE can be managed by a skilled nursing staff in a quiet medical ward, with minimal stimulation to the patient. Regular neurologic assessments should be performed because HE may progress rapidly to grade 3 or 4 with severe CE and potential irreversible consequences. It is important to evaluate and treat factors such as electrolyte abnormalities, bleeding, and infection. Head imaging with computerized tomography is only useful if intracranial hemorrhage is suspected. Magnetic resonance imaging of the brain should be avoided because of prolonged scanning time in a confused or agitated patient. Avoidance of sedatives and narcotics is recommended to accurately follow the patient’s mental status. However, treatment with short-acting benzodiazepines or propofol may be necessary for cases with extreme agitation. If high-grade HE is suspected, an arterial ammonia level may be useful. Ammonia is an independent risk factor for the development of intracranial hypertension. A level >100 µmol per L predicts severe encephalopathy with 70% accuracy, and a level of 200 µmol per L is associated with intracranial hypertension in half of the ALF patients [38]. Patients with persistent arterial hyperammonemia (>122 µmol per L) for 3 days were more likely to progress and maintain high-grade HE with lower rates of survival (23% vs. 72%), higher incidence of CE (71% vs. 37%), and seizures (41% vs. 7.7%) [39]. Intubation should be performed for airway protection and support with mechanical ventilation when the patient becomes somnolent or develops respiratory distress as a result of metabolic acidosis. Standard therapy for HE of chronic liver disease, such as lactulose, neomycin, or rifaximin, have no proven benefits in ALF and can induce deleterious side effects such as bloating, abdominal pain, nausea, and electrolyte disturbances from diarrheal losses [3].

CE is a devastating complication of ALF. Improvements allowing early recognition, critical care, and the use of emergency LT positively affect the incidence and outcomes of CE. The proportion of patients with intracranial hypertension fell from 76% in 1984 to 1988 to 20% in 2004 to 2008. More importantly, mortality declined from 95% to 55% [40]. The pathophysiology of CE is multifactorial, but ammonia is recognized to play a central role in the development of HE and CE. The liver

metabolizes ammonia to urea during homeostasis. Liver failure results in hyperammonemia and ammonia easily crosses the blood–brain barrier. Astrocytes are the only cells in the brain that can metabolize ammonia. Glutamine synthetase in astrocytes converts glutamate and ammonia to glutamine. Glutamine accumulates and acts as an osmolyte and increases astrocyte volume which then contributes to CE \[41\]. Alternatively, inflammatory cytokines and toxic products from the necrotic liver are proposed to mediate neuroinflammation in ALF. Proinflammatory cytokines have the capacity to alter blood–brain barrier integrity, activate microglia, and act synergistically with ammonia to further cause vasogenic brain edema \[41,42\].

The most accurate method of diagnosing intracranial hypertension is with the insertion of an ICP monitor. Some centers use ICP monitoring when patients develop grades 3 and 4 HE to help guide management. The normal ICP is 5 to 10 mm Hg and clinically relevant intracranial hypertension exceeds 20 mm Hg. Monitoring mean arterial pressures (MAPs) and maintaining cerebral perfusion pressures (MAP minus ICP) are important. Ideally, ICP should be maintained around 15 mm Hg, with cerebral perfusion pressures greater than 40 to 50 mm Hg. Recovery of neurologic function is optimized by maintaining cerebral perfusion pressures >40 mm Hg. Noninvasive or indirect ICP monitoring such as transcranial Doppler \[43–45\], transcranial near-infrared spectroscopy \[46\], jugular venous oximetry \[47\], and ultrasonic measures of optic nerve sheath diameter \[44\] had been reported in ALF, but their availability and clinical experience with these monitors are limited.

The use of intracranial pressure monitoring devices in patients with ALF is controversial because of a small but potentially life-threatening risk of intracranial hemorrhage. Practices vary widely based on local transplant center expertise. A review of ICP monitoring in 24 US centers reported ICP monitoring in only 28% of patients with ALF, but the frequency of monitoring significantly differed among centers. Complications of intracranial hemorrhage occurred in 10.3% and may have contributed to the death of two patients. The 30-day survival post-liver transplant was similar in both monitored and nonmonitored groups \[48\]. A recent retrospective cohort study from the US Acute Liver Failure Study group reported absence of 21-day survival benefit in acetaminophen-ALF and worse outcomes for non-acetaminophen ALF. These results occurred in ICP-monitored patients despite increased intracranial hypertension-directed therapies and more patients receiving liver transplant (41% vs. 18%). Hemorrhagic complications were rare and
do not account for the outcomes [49]. Seizures can increase intracranial pressure and should be promptly controlled with phenytoin; however, routine seizure prophylactic treatment is not recommended. In the absence of ICP monitoring, bedside assessment with frequent neurologic evaluation cannot be overstated. The early clinical manifestations of CE often overlap with advanced encephalopathy (grades 3 and 4). The most feared complications are brain herniation and death. Frequent evaluation of mental status (avoiding sedation and neuromuscular blockade if possible), assessment for hyperreflexia, pupillary changes, and sudden systemic hypertension play an important role in monitoring these very ill patients. Prolonged low cerebral perfusion or intracranial hypertension leading to cerebral ischemia and death or a large intracranial bleeding from an underlying coagulopathy eliminates the possibility of transplantation.

Simple recognized strategies to control CE include elevation of the head of the bed to 30° to improve venous drainage, minimization of external stimuli, control of fever and maintaining serum sodium between 145 and 155 mmol per L. IV hypertonic saline continuous infusion rather than boluses (5 to 20 mL 30% saline) should be used [50]. If intracranial hypertension develops despite these prophylactic methods, IV administration of mannitol (100 mL of 20% solution given IV at 0.25 to 0.5 g per kg) can be used as a first-line treatment when ICP is persistently >20 mm Hg for over 10 minutes [51]. Mannitol draws water osmotically from swollen astrocytes back into the intravascular space. It should be avoided in patients with renal failure because of the potential for intravascular volume overload and pulmonary edema. This can be obviated by starting continuous veno-venous hemofiltration. Additional doses of mannitol may be given again as long as the serum osmolality is <320 mOsm per L. The minor survival benefit of mannitol has been shown only in a small series and there are no benefits for cases of severe intracranial hypertension, i.e., >60 mm Hg [52].

Administration of corticosteroids such as dexamethasone has failed to show any benefit in treating elevated ICP [52]. Hypothermia (32°C to 35°C) reduces the production of inflammatory mediators, decreases arterial and cerebrospinal spinal fluid ammonia levels, and attenuates ICP. An earlier small series showed that moderate hypothermia may be effective and safe in patients awaiting liver transplant with intracranial hypertension refractory to standard medical therapy [53]. This result was not duplicated when a retrospective controlled study on moderate hypothermia looked at the impact on survival in ALF patients with high risk of CE. Although no increase in bleeding or infection was seen for therapeutic hypothermia, no effect on 21-day survival was demonstrated [54].

Definitive treatment of CE or intracranial hypertension is achieved
with emergency LT. Despite the most appropriate care and stringent inclusion criteria, residual neurologic deficits may persist after transplantation.

Respiratory Complications

Acute lung injury or acute respiratory distress syndrome may be seen in 40% of patients with ALF, and a significant proportion of patients with CE may develop pulmonary edema [55]. Although ALF may have a direct effect in inducing neurogenic pulmonary edema, other etiologies could potentially include aspiration pneumonia, nosocomial pneumonia, transfusion-related lung injury, and intra-alveolar hemorrhage. These patients should be treated with supplemental oxygen or endotracheal intubation as clinically indicated. Intubation, however, is used more frequently for airway protection rather than for respiratory failure. Rapid sequence intubation technique should be used to avoid worsening intracranial hypertension, and nondepolarizing agent cisatracurium is preferable to succinylcholine to avoid muscle contraction which can increase ICP. For sedation, the preferred agent is propofol at 30 to 50 µg/kg/min because of the purported benefits in reducing ICP [56]. Positive pressure ventilation should be used to optimize compliance with caution because the resulting decreased vascular return can lead to increased ICP and cardiac output. The combination of rising ICP and metabolic acidosis in patients with ALF leads to a compensatory hyperventilation and hypocapnia. Forced hyperventilation to PaCO₂ of 25 to 30 mm Hg to restore cerebrovascular autoregulation, induce cerebral vasoconstriction, and reduce ICP is not recommended because it showed no impact on reducing the incidence of CE or a survival benefit [57]. Potential worsening of CE caused by cerebral hypoxia secondary to vasoconstriction further limits its utility.

Acute Kidney Injury

The development of acute kidney injury (AKI) is a common complication of ALF and deemed a poor prognostic indicator in ALF. Overall, as many as 70% of patients with ALF developed AKI and 30% received renal replacement therapy (RRT) [58].

AKI etiologies include hepatorenal syndrome, acute tubular necrosis either from sepsis or drug toxicity, and prerenal azotemia. For acetaminophen-induced ALF, a significant proportion of patients develop acute renal failure from direct renal toxicity of NAPQI. Diagnosis of the etiology of AKI requires close monitoring of urine output, volume status, and measurement of urinary sodium and creatinine. Urinary sodium and creatinine can help identify the presence of acute tubular necrosis (high
or normal urine sodium) but cannot differentiate between prerenal azotemia and hepatorenal syndrome type 1 (low urine sodium < 10 mmol). Nephrotoxic agents should be avoided in renal failure, and careful renal dosing of medications is vital.

RRT is often initiated early for patients with oliguric renal failure and ALF to prevent complications of volume overload and the risk of intracranial hypertension. The risks of RRT include line sepsis, bleeding, and medication under dosing [59]. Placement of a line under ultrasound guidance may avoid the Trendelenburg position for patients at risk of CE [60]. Citrate anticoagulation is recommended because of high risk of bleeding in ALF, and patients should be monitored for citrate lock wherein hypocalcemia occurs as a result of the formation of calcium citrate complexes in the blood. ALF patients are particularly vulnerable because the liver is unable to metabolize citrate to bicarbonate and patients receive citrate from blood products. It is important to consider adjustments in the dose of NAC (dose increase) in patients on RRT because NAC is dialyzable [61]. As expected, survival was decreased in patients receiving RRT compared to patients without AKI (57% vs. 93%). However, even though AKI is common, it rarely results in chronic kidney disease among patients who survive. Only 4% of patients requiring RRT became dependent on dialysis [58].

---

**Metabolic Disorders**

Multiple metabolic derangements occur in ALF. Hyponatremia may occur with volume depletion and as a result of severe splanchnic vasodilation and activation of the renin–angiotensin system. Rapid correction of the serum sodium should be avoided because of the risk of osmotic demyelination syndrome. Metabolic acidosis and alkalosis can occur concurrently. Lactic acidosis is a severe metabolic complication and is widely associated with poor outcomes [62]. Sepsis is an important cause of lactic acidosis that needs proper evaluation. Serum lactate accumulates as a result of tissue hypoxia from hypotension as well as impaired hepatic uptake and metabolism of lactate. Renal dysfunction can further exacerbate metabolic acidosis. Initial treatment involves fluid resuscitation. For metabolic acidosis, half-normal saline with bicarbonate may be required while awaiting RRT [63]. Caution should be taken to avoid volume overload. Hypoglycemia also frequently complicates ALF, given the primary metabolic role of the liver for glycogen storage and gluconeogenesis. Massive hepatic damage is required before serum glucose drops to levels that impair neurologic and cellular function.
Frequent glucose monitoring and infusion of concentrated dextrose solutions may be required. Close monitoring of potassium, magnesium, and phosphate levels is likewise necessary. Hypophosphatemia is frequent in ALF and requires aggressive replacement.

**Coagulopathy**

Coagulopathy is a feature of ALF. The liver synthesizes nearly all circulating coagulation factors and inhibitors, including protein C and protein S, and thrombopoietin, which are essential for platelet production. Laboratory tests such as the prothrombin time (PT), INR, and activated partial thromboplastin time (aPTT) are all prolonged. These parameters are typically followed to monitor hepatic function recovery (in the absence of fresh frozen plasma administration). Clinically significant spontaneous bleeding in ALF is rare [64]. Because of concomitant changes in both procoagulant and anticoagulant pathways, in acute and chronic liver failure, there is a paradoxical state of bleeding and thrombosis in these patients [65]. There is growing evidence of preserved hemostasis in acute liver injury/ALF despite elevated coagulation parameters [66]. Recombinant activated factor VII (rFVIIa) has emerged as a potential treatment and prophylaxis option for bleeding in patients with liver disease. However, prophylactic use of rFVIIa is not the current standard of care. The high cost of rFVIIa as well as the risk of thromboembolic events limits its effectiveness for prophylaxis. The use of rFVIIa in ALF for the rapid correction of INR before an invasive procedure such as placement of an ICP monitor can be advocated in patients who may have CE [67].

GI and oropharyngeal bleeding can result from stress-related mucosal injury. Protection of the gastric mucosa with proton pump inhibitors or H₂ receptor antagonists to prevent mucosal bleeding should be initiated at the onset of coagulopathy. The skin, lungs, and urogenital tract are also potential sites of significant blood loss. Transfusion of blood and blood products are only indicated in patients before invasive procedures or when clinically significant bleeding occurs. Because of the risk of worsening CE and fluid overload with transfusion-related lung injury, use of blood products must be judicious. The effects of fresh frozen plasma on INR are modest and short-lived. In our practice, fresh frozen plasma is infused immediately prior and during procedures to attenuate the risks of bleeding. A single slow infusion of vitamin K 10 mg IV rather than oral form should be given in ALF because vitamin K deficiency has been reported in these patients and intestinal absorption can be unreliable [68]. There are no guidelines for platelet and coagulation transfusion parameters. In the absence of bleeding, a platelet threshold of 10,000 per μL has been recommended and 50,000 per μL or higher when invasive
procedures are anticipated. PT, INR, and aPTT cannot adequately predict the bleeding risk in liver disease because of the insensitivity of these tests to the protein C pathway, antithrombin, and tissue factor pathway inhibitor [69,70].

Hemodynamic and Cardiac Complications

Elevated cardiac output (hyperdynamic circulation), decreased peripheral oxygen extraction (tissue hypoxia), and low systemic vascular resistance are present in patients with liver failure. These hemodynamic parameters, possibly because of the release of vasoactive mediators from dying hepatocytes, are similar to those found in patients with sepsis. Splanchnic and peripheral vasodilatation leading to systemic hypotension should be treated with volume replacement. Central venous pressure may be useful in assessing and correcting fluid status in these patients. MAP should be maintained above 65 mm Hg [51]. Norepinephrine is the preferred primary vasopressor because it minimizes tachycardia and preserves splanchnic blood flow. Vasopressin at a fixed rate may be added in refractory cases of hypotension but with caution if CE is suspected. A progressive rise in systolic blood pressure (hypertension) accompanied by bradycardia and widening pulse pressure (Cushing triad), within minutes or hours, can be indicative of intracranial hypertension and impending uncal herniation. Persistent hypotension despite adequate volume resuscitation or empiric broad-spectrum antibiotics should raise concern for adrenal insufficiency. Adrenal insufficiency is common in ALF and correlates with disease severity and should be treated with hydrocortisone 200 to 300 mg per day [71].

Sepsis

Infection commonly occurs in ALF; however, the diagnosis is often difficult as a result of the overlapping hemodynamic changes induced by the liver failure; at times, patients may not demonstrate leukocytosis or fever. The progression of AKI and the worsening of HE should raise the suspicion for infection, and adequate evaluation should be undertaken. The urinary tract and pulmonary system are the most frequent sources of infection. Skin wounds, indwelling vascular access catheters, and ICP monitors are also potential sources of infection. The most common organisms identified are Staphylococcus, Streptococcus, Gram-negative organisms, and Candida species. Fungal infections occur late in the course of illness and are associated with high mortality. Because the hemodynamic, metabolic, and hematologic parameters of ALF are often indistinguishable from sepsis, hospital staff must maintain a high level of suspicion for infectious complications. Because sepsis may be easily overlooked, periodic surveillance cultures (chest radiography, sputum,
and urine and blood cultures for fungal and bacterial organisms) can be helpful. However, the routine use of prophylactic antibiotics is controversial and was not shown to reduce the incidence of bloodstream infection or improve 21-day mortality; although, more patients who received prophylactic antibiotics received liver transplants. Multivariable analysis after controlling for confounding showed that antimicrobial prophylaxis did not confer a significant effect on 21-day mortality [72]. Empiric antibiotic and antifungal treatment should be initiated if progression of HE or elements of systemic inflammatory response system (SIRS) is observed. Systemic fungal infection is widely viewed as a contraindication to LT. Transplantation eligibility for patients with evidence of infection and receiving antibiotic treatment is generally reviewed on a case-by-case basis.

Prognosis

Prognostic factors in patients with ALF had been investigated to determine patient survival. Improper selection of a liver transplant recipient who nonetheless will survive with supportive care because of liver regeneration will unnecessarily subject the patient to the morbidity and mortality of transplantation, commit an individual to lifelong immunosuppression, and preclude another medically deserving patient from receiving a LT. Even more crucial is identifying the ALF patient who would die without emergency LT. As a result, several predictive models had been proposed to solve this dilemma.

Among the many predictive models, King’s College criteria remain widely used because of the readily available parameters and high specificity for selecting the appropriate patient who will need emergency LT. The King’s College criteria produced the first prognosis model in 1989 for both acetaminophen-induced and non-acetaminophen liver failure (Table 207.4). The addition of elevated lactate levels (>3.5 mmol per L) on admission further improved the sensitivity of the model to predict mortality in acetaminophen-induced liver failure [73]. Two recent meta-analyses evaluated the performance of King’s College Criteria and found specificity of 82% and 95% but sensitivity of 68% and 58%, respectively [74,75]. Although the King’s College criteria are useful wherein a patient meeting its criteria will most assuredly require a liver transplant for survival because of its high specificity, the low sensitivity (58% to 68%) observed implies that a proportion of patients who do not meet the King’s College criteria may actually have poor prognosis, may be missed, and not offered emergency LT. Other prognostic models had been proposed.
for ALF, and they are often reevaluated and modified: MELD [76], sequential organ failure assessment (SOFA) [77], Clichy criteria [78,79], and acute physiology and chronic health evaluation (APACHE) 2 [80]. Although these models overall are useful for identifying patients who will likely need a LT because of poor prognosis (high specificities), the sensitivities of these models are low and reliance on these models alone is not recommended [81].

ACUTE-ON-CHRONIC LIVER FAILURE

Definition and Features

ACLF is defined as an acute deterioration of preexisting chronic liver disease, usually related to a precipitating event and associated with increased 3-month mortality caused by multisystem organ failure [82]. Precipitating events may be viral hepatitis, such as reactivation hepatitis B (typically in Asia) and drug- or alcohol-associated hepatitis or variceal hemorrhage in the West. A multidisciplinary approach involving both the critical care and hepatology teams is recommended. [83]. Hyperbilirubinemia and coagulopathy are chief among the sign/symptoms of ACLF. Bilirubin ≥ 19.9 mg per dL and INR > 2.5 are independent predictors of mortality for this population, as is prior liver decompensation within 6 months [84]. Organ failure is a cardinal feature that often involves the kidneys, brain, heart, lungs, and circulatory and hematologic systems. Development of each new organ failure, renal failure, and the need for inotropic support is associated with increased mortality [84]. SIRS is commonly present and is predictive of mortality especially when associated with renal failure [85].

Treatment and Management Options

There is no single treatment for ACLF. Identification of the precipitating event, directed treatment, prevention of further injury, and supportive care is the standard approach. Integral components to supportive care, when indicated, include mechanical ventilation, vasopressor support, RRT, empiric antibiotics, albumin, and blood products.

Liver support devices have attracted much publicity as a possible treatment option for these patients. The best studied devices are the Prometheus and molecular adsorbents recirculating system (MARS). Unfortunately, studies of these devices have failed to detect mortality benefit of their use. A study of the Prometheus device showed that it was well tolerated and successful at decreasing serum bilirubin level, but with unchanged survival at 28 and 90 days when compared to those who did not undergo this therapy [86]. It was demonstrated that the subgroup of patients with a MELD >30 had improved survival benefit; no further studies have been specifically designed to address this question, and the validity of this results remains unclear [86]. A study of the MARS device showed that it was a well-tolerated procedure, with no increase in adverse events and improvement in serum bilirubin and creatinine; but similarly, no improvement in mortality was seen at 28 or 90 days [87]. The benefits
in the subgroup with higher MELD scores were not seen.

Granulocyte colony-stimulating factor (GCSF) is an immunomodulator glycoprotein that was observed in animal models to promote hepatic repair [88], ameliorates hepatic damage, and accelerates regeneration [89]. A study has reported mortality benefits with GCSF compared to placebo at 60 days, as well as improvements in Child–Turcotte–Pugh (CPT), MELD, and SOFA scores [90]. Importantly, a statistically significant decreased risk for development of hepatorenal syndrome, encephalopathy, and sepsis was reported for those treated with GCSF [90]. Moreover, it continues to show promise for the treatment of ACLF owing to reactivation hepatitis B [91] and severe alcoholic hepatitis [92] with some short-term survival benefits.

LT remains controversial for this group of patients because many of the patients have comorbid substance abuse or psychiatric conditions. However, in a retrospective study, there was no increase in mortality posttransplantation among those with ACLF compared to those with chronic liver failure alone [93]. Thus, transplantation for this group may be appropriate with proper identification of candidates.
LIVER TRANSPLANTATION

Patients with ALF and a life expectancy of less than 7 days are deemed to have FHF and granted MELD exception status 1A and priority for LT over patients with chronic liver disease. Criteria for listing include the absence of underlying liver disease, encephalopathy within 8 weeks of the onset of liver disease, an INR > 2, or requirement for RRT or ventilator dependence [94]. A patient with acute decompensated Wilson disease is also granted status 1A as a result of poor survival without a liver transplant. Selection also must discriminate the appropriate patient who would die without a transplant from the patient who is too sick for transplant and the patient who would likely recover only with supportive care. Psychosocial factors are likewise important for determining eligibility and are necessary components of transplant evaluation. Medical contraindications to liver transplant include evidence of uncal herniation, uncontrolled infection despite antibiotic therapy, multiple pressor requirement and multiorgan failure. Failure to recover neurologic function after LT is extremely worrisome but fortunately uncommon. There are reports of regrafting these livers to second recipients with success. In Asia, where living donors are the main source of organs, long-term outcomes of living donor LT for ALF are excellent, regardless of the etiology or classification [95]. In the United States where there is an established system of nonliving donation, the ethical dilemma of donor safety, coercion for donation, and informed consent are debated questions. Auxiliary LT wherein a whole, partial, or hemiliver is transplanted in ALF patients whereas the native liver remains in situ as a bridge to survival, is a technically demanding method that is only practiced in a handful of centers, mostly in Europe (only performed in 2% of cases) [96]. The concept is based on the liver’s ability to regenerate completely after ALF, circumventing the need for lifelong immunosuppression.

Significant improvements of outcomes for patients who received liver transplant for ALF had been reported. In the United Kingdom, 1-year survival improved from 63% in 1994 to 1999 to 79% in 2000 to 2004 [97]. In the US ALF study group (patients 1998 to 2010), the longer term survival in ALF liver transplant recipients was excellent (92.4%) and significantly better than that of those patients who did not require a transplant (89.5%) for acetaminophen and 75.5% non-acetaminophen ALF [98].

8. Fontana RJ, Ellerbe C, Durkalski VE, et al: Two-year outcomes in initial survivors with acute liver failure: results from a prospective,
A wide spectrum of acute biliary tract diseases may be seen in the intensive care unit (ICU). Presentations vary from mildly abnormal blood chemistries to life-threatening septic shock. Unrecognized biliary disease can lead to significant morbidity. A practical approach to evaluate and treat biliary disorders using a wide array of noninvasive and invasive diagnostic and therapeutic aids is of paramount importance.

The anatomy of the biliary tract is depicted in Figure 208.1. Approximately 500 mL of bile is secreted at the level of the canaliculus each day. Bile flows through progressively larger ductules until reaching the main bile ducts. The bile duct courses through or immediately adjacent to the head of the pancreas in more than 90% of patients. Hence, any pathology in the head of the pancreas can result in biliary obstruction. Bile flow into the duodenum is regulated by the sphincter of Oddi, which consists of muscle fibers that surround the distal bile duct in the wall of the duodenum at the major ampulla. Tonic contraction of the sphincter increases pressure in the common bile duct (CBD) and allows the gallbladder to fill in a retrograde fashion through the cystic duct. A gallstone passing from the gallbladder to the duodenum would typically encounter resistance to passage in the region of the cystic duct and at the sphincter of Oddi. Biliary tree pathology can be diagnosed by transabdominal ultrasonography, computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), or endoscopic ultrasonography (EUS). Access to the biliary tree for therapeutic purposes may be obtained through ERCP, EUS, percutaneously, or open surgery.
FIGURE 208.1 Normal anatomy of the biliary tract.

DIAGNOSTIC EVALUATION

Physical Examination

Physical signs of patients with biliary tract disease may encompass a spectrum from the acute abdomen to nonspecific findings including ileus, fever, or sepsis with hemodynamic instability. Physical exam may reveal icterus, hepatomegaly, ascites, or focal right upper quadrant tenderness.

Laboratory Evaluation

For the obtunded or otherwise compromised ICU patient, abnormal laboratory values often are the first clue to biliary tract disease. All ICU patients should have appropriate laboratory testing on admission, including serum bilirubin, alkaline phosphatase, and transaminases (aspartate aminotransferase or alanine aminotransferase). Bilirubin
elevation may indicate an obstructive biliary process, but other processes such as sepsis, drug effects, hemolysis, or other nonbiliary etiologies should be considered for an acutely ill patient. Alkaline phosphatase elevation is not specific for biliary disease; concomitant elevation of γ-glutamyltransferase helps to confirm its hepatobiliary origin. Serum transaminase elevations are the hallmark of hepatocellular injury. However, an elevation in transaminases can also be seen in patients with bile duct obstruction and may precede bilirubin and alkaline phosphatase elevation in the acute setting. Occasionally, laboratory evaluation can be normal as in cholecystitis, without involvement of the CBD and without substantial pericholecystitic hepatitis.

Noninvasive Imaging Studies
Noninvasive radiologic imaging is essential for the evaluation of patients with suspected biliary tract disease.

Plain Abdominal Radiograph
The plain radiographic features of biliary tract disease are usually nonspecific [1]. The most common bowel gas finding seen among patients with acute biliary disease is a generalized ileus. Gallstones are rarely detected on plain radiographs because only 20% of stones are radiopaque. Air in the biliary tree may result from a biliary-enteric fistula or surgical anastomosis, prior sphincterotomy, or infection with gas-producing organisms.

Ultrasonography
Ultrasonography is the initial diagnostic test of choice in the ICU setting and can be performed at the bedside with good results [2]. It is a sensitive test for determining biliary ductal dilatation, acute cholecystitis, and >95% accuracy in detecting cholelithiasis. However, it has low sensitivity (25% to 60%) for detecting choledocholithiasis [3] because gas in the duodenum can obscure visualization of the distal bile duct. In the presence of cholelithiasis or gallbladder sludge, the findings of ductal dilatation, elevated liver enzymes, abdominal pain, and fever are strongly suggestive of cholangitis. Findings on ultrasonography that may indicate acute gallbladder disease include focal tenderness over the gallbladder, thickening of the gallbladder wall, and pericholecystitic fluid collections, but none is specific for cholecystitis. The technique may also detect other abnormalities, including liver lesions, pancreatic masses, abscesses, or ascites.
Radionuclide Scanning

Technetium-99m-labeled hepatic iminodiacetic acid (HIDA) scan yields physiologic and structural information regarding the biliary tract. Filling the gallbladder with radionuclide confirms cystic duct patency, virtually excluding the diagnosis of acute cholecystitis. False-positive examinations can be seen in patients with chronic cholecystitis, on long-term parenteral nutrition, or after prolonged fasting. Delayed views and routine pretreatment with cholecystokinin increase the accuracy of technetium-99m-labeled HIDA scanning for acute cholecystitis to greater than 93% [4]. Radionuclide scanning is also useful in identifying structural abnormalities of the biliary tree, such as significant bile duct leaks; evidence of radiotracer in the abdominal cavity is diagnostic of bile leak. It has a limited role in patients with poor hepatocellular function, complete biliary obstruction, or cholangitis, each of which prevents adequate uptake or excretion of the radiopharmaceutical into the biliary tree.

Computed Tomography

CT scanning has low sensitivity for the detection of choledocholithiasis and is used primarily to document biliary dilation, to exclude other causes of biliary obstruction (e.g., a mass lesion), and to detect local complications such as liver abscess. Unlike ultrasonography or radionuclide scanning, CT cannot be used portably in the ICU. Findings on CT for gallbladder disease include thickening of the gallbladder wall, pericholecystitic fluid, and adjacent abscesses. In addition, CT may reveal a biloma or free fluid in the abdomen. It also allows detailed visualization of the pancreas for grading the severity of pancreatitis and assessing its complications, such as necrosis or pseudocyst formation.

Magnetic Resonance Imaging

The use of magnetic resonance cholangiopancreatogram images can be manipulated to display highly accurate representations of the pancreaticobiliary system with high sensitivity (88% to 96%) and specificity (93% to 100%) for the diagnosis of choledocholithiasis [5], strictures, and tumors. It has limited value for detecting stones <6 mm, impacted stone at the ampulla, and dilated bile duct >10 mm [6]. Its use is limited when patients are too sick for transport to the radiology suite.
Summary

When evaluating the ICU patient with suspected biliary tract disease, ultrasonography should be the initial procedure of choice, followed by hepatobiliary scanning if cystic duct obstruction or bile leakage is suspected. Both are portable and noninvasive. Ultrasonography is highly accurate for the detection of gallstones and structural pathology. Hepatobiliary scanning, on the contrary, provides physiologic information, primarily regarding patency of the cystic duct. Functional information can be especially important for patients with suspected calculous or acalculous cholecystitis. CT or MRI should be reserved for those patients in whom sonographic or radionuclide findings are equivocal, if other intra-abdominal pathology needs to be excluded, or if ductal dilatation is seen on ultrasonography without a clearly defined etiology.

Invasive Diagnostic Testing

Endoscopic Retrograde Cholangiopancreatography

The technique of ERCP is used for both diagnostic and therapeutic purposes as described in Chapter 20. In brief, a side-viewing endoscope is passed through the mouth into the second duodenum, where the major ampulla is identified and cannulated. The biliary tree is then opacified with contrast injected through a catheter, allowing a retrograde cholangiogram to be obtained. Fluoroscopy and standard radiographs are used to examine the biliary tree and define abnormalities including stones, strictures, leaks, and obstruction. Endoscopic therapy, including stone removal, biliary drainage, or stricture dilatation, can be accomplished in the same setting. ERCP can be used for the evaluation and therapy of the ICU patient, especially if the patient can be stabilized for endoscopy and transported to a fluoroscopy room. Rarely is it necessary to perform emergent biliary decompression at the bedside using portable fluoroscopy. Coagulopathies should be corrected before the procedure, especially if an endoscopic sphincterotomy (electrocautery incision of the sphincter of Oddi in the duodenal wall for stone removal or drainage) is anticipated. If coagulopathies cannot be satisfactorily corrected, a stent can be placed into the bile duct to allow drainage without performing a sphincterotomy. Major morbidity from the diagnostic procedure includes pancreatitis, cholangitis, perforation, and hemorrhage. The complication rates of ERCP in a recent review noted reduced rates, compared with prior reporting, of pancreatitis at 3.5%, infection at 1.4%, and perforation at 0.6% under standard conditions [7]. The value of ERCP is largely operator-dependent and can be highly
successful in the delineation and treatment of biliary disease in the ICU patient [8].

**Endoscopic Ultrasonography**

EUS involves the transoral passage of an endoscope with an ultrasonic transducer at the tip. The limitations of transabdominal ultrasonography are overcome with this modality because all areas of the biliary tree, including the intrapancreatic portion of the bile duct as well as the pancreas, can be imaged without interference from gas in the intestines. EUS can reliably identify cholelithiasis and is more sensitive than transabdominal ultrasonography in detecting choledocholithiasis with a sensitivity of 95%, specificity of 98%, and an accuracy of 96%. Compared to MRCP, EUS has the additional benefit of being able to detect smaller (<5 mm) stones in small caliber bile ducts [9]. Although EUS is typically an elective procedure and uncommonly used in the ICU, the test may be useful for identifying those patients who would benefit from endoscopic stone extraction by ERCP [10], in particular when clinical predictors of biliary obstruction such as cholestatic liver enzymes and dilated CBD by ultrasonography or CT are unreliable for predicting the presence of CBD stones in the early stages of acute gallstone pancreatitis [11].

**Percutaneous Transhepatic Cholangiography**

Percutaneous transhepatic cholangiography (PTC) requires fluoroscopy to guide passage of a needle into the intrahepatic bile ducts. The biliary tree is then filled with contrast, and images are obtained. The use of PTC as a diagnostic test has been supplanted by ERCP and noninvasive examinations discussed previously. Currently, PTC is used primarily as an initial step of percutaneous transhepatic biliary drainage. Decompression of the biliary tree via a percutaneous catheter is a highly effective method for rapid nonoperative and nonendoscopic biliary decompression. This procedure is indicated when a patient requires emergent biliary drainage but is not stable enough to undergo ERCP under conscious sedation, if the major papilla cannot be reached endoscopically because of postsurgical anatomy or a technical failure in cannulating the bile duct. The technique involves an initial PTC to delineate the biliary anatomy, followed by selective cannulation of an appropriate intrahepatic bile duct with an 18-gauge needle. A guidewire is then passed into the biliary tree, the tract is dilated, and a drainage catheter is placed. Successful drainage can be established in almost all patients. Percutaneous biliary drainage is an invasive procedure, and acute complications, including hemorrhage, sepsis, and bile leakage, occur in 1% to 5% of patients [12].
Percutaneous Liver Biopsy

Liver biopsy is an important technique for the evaluation of selected patients with hepatobiliary abnormalities who do not have obvious biliary ductal dilatation. Liver biopsy may lead to a rapid pathologic diagnosis in patients with intrinsic liver disease. In cases of infection, tissue can also be cultured. In patients with a coagulopathy, a liver biopsy may be obtained by way of the hepatic vein using a transjugular approach or percutaneously using a sheath, embolizing the tract after completion of the biopsy [13].
Acute Cholangitis

Acute cholangitis is a life-threatening illness. The presentation of patients with cholangitis may range from intermittent low-grade fever to fulminant septic shock. This diagnosis must be considered and excluded in all patients who present to the ICU with shock and sepsis of unknown origin because of the high mortality if urgent biliary decompression is not accomplished. It occurs as a consequence of partial or complete biliary tract obstruction, typically in patients with biliary stasis in the presence of bacterobilia secondary to stones, strictures, or recent manipulations of the biliary tree [6]. Bacteremia or endotoxemia is correlated directly with the elevated intrabiliary pressure that allows reflux of bacteria into the bloodstream.

Acute cholangitis is a clinical syndrome characterized by fever, jaundice, and abdominal pain (Charcot triad) present in 15% to 72% of patients [14]. Reynold pentad (Charcot triad with the addition of hypotension and altered mental status) may be seen in only 4% to 8% of patients with cholangitis. Liver enzymes are invariably elevated, with a widely variable range. Blood cultures are positive in 21% to 71% [15,16], and gram-negative isolates of Escherichia coli, Klebsiella, and Enterococcus are found most commonly. Anaerobic bacteria are isolated more commonly in polymicrobial infections in patients who have had prior biliary-enteric surgery, are elderly, or have severe disease [6]. Patients who have had recent biliary surgery or who have indwelling stents are more likely to harbor Enterococcus, hospital-acquired organisms, or fungi [17].

Because most patients with cholangitis will demonstrate gallstones or a dilated biliary tree, an abdominal ultrasound is the best initial evaluation. This, in association with elevated liver enzymes, fever, or sepsis, is strongly indicative of this diagnosis and should prompt early consultation for decompression.

Treatment

Once cholangitis is suspected, the patient should be treated empirically with broad-spectrum antibiotics with adequate biliary excretion such as
ampicillin/sulbactam, piperacillin/tazobactam, third- or fourth-generation cephalosporins, a quinolone, or a carbapenem. Patients who have mild disease usually respond promptly to medical therapy and should undergo biliary decompression and/or definitive therapy for bile duct stones as early as possible, preferably within 24 to 48 hours. Patients who have severe or progressive obstructive biliary disease require urgent biliary drainage in addition to medical therapy. Delay in securing biliary drainage in this subgroup may produce a fatal outcome. This can be accomplished by endoscopic, percutaneous, or surgical means. Selection of a particular approach should be tailored to the patient’s condition, local expertise, and the rapid availability of the procedure. Initial efforts for decompensated patients should concentrate on decompression of the biliary tree through ERCP or percutaneous drainage. Definitive therapy may be accomplished at a later time, even if this requires a second procedure. It must be recognized that even with modern support, biliary decompression techniques, and broad-spectrum antibiotics, the mortality from acute fulminant cholangitis ranges from 10% to 50%.

Biliary Obstruction

Biliary obstruction may present without cholangitis. The multiple causes of biliary obstruction are listed in Table 208.1, the most common being stone disease, benign stricture, and malignancy. The patient with physical findings and laboratory studies suggesting obstruction should initially be evaluated with noninvasive imaging or EUS to define the level of obstruction and determine the etiology for definitive therapy planning.

Biliary obstruction without cholangitis is seen more often with malignancy than with stone disease or inflammatory strictures. Definitive therapy for stone disease and benign strictures as well as palliative therapy for malignant strictures may be accomplished utilizing ERCP or PTC. Surgical approaches are preferred for patients who are good operative candidates and who may have resectable malignancy. Bile duct stenting often serves as a bridge to surgery for these patients.

p. 2053
p. 2054

Bile Leak

A bile leak may be seen after open or laparoscopic cholecystectomy, hepatic resection, liver transplantation, liver biopsy, PTC, or liver laceration owing to blunt or penetrating trauma. In the postcholecystectomy setting, the most common site of leak is the cystic duct stump; however, leak from the accessory ducts of Luschka, CBD, common hepatic duct, or the liver bed also occurs [18]. The extravasated bile may accumulate focally to form a biloma or freely flow within the peritoneal cavity. The resultant bile peritonitis is usually associated with abdominal pain, ascites, leukocytosis, and fever. Occasionally, collections of bile become infected, resulting in an abscess if untreated. Seldom, patients may present solely with new-onset ascites and an elevated serum bilirubin level. Diagnosis of a biliary leak can usually be made with hepatobiliary scanning. Ultrasonography and CT may reveal a biloma or free fluid in the abdominal cavity. This can be followed by ERCP to determine the exact location of the leak and provide definitive therapy.

Patients with suspected bile leak should be placed on broad-spectrum antibiotics, and the presence of a bile leak should be confirmed with hepatobiliary scanning followed by ERCP. ERCP with therapeutic intent should be performed as soon as possible after diagnosis to limit the degree of bile leakage and patient symptoms. The aim of endoscopic therapy is to decrease or abolish the tone of the sphincter of Oddi, which diverts bile flow away from the leak site. This can be achieved with ERCP and stent placement, with or without sphincterotomy. Stent placement
alone is preferred for patients at high risk of post-ES bleeding [19]. Rarely, if endoscopic therapy is unsuccessful for healing a bile leak, surgical repair may be required.

**Acute Cholecystitis**

Acute cholecystitis is a frequent and important event that occurs in the ICU. The signs and symptoms of acute cholecystitis are often not readily apparent in the compromised ICU patient. A high degree of suspicion and prompt use of noninvasive testing, including ultrasonography and hepatobiliary scanning, are essential to arrive at a timely and correct diagnosis of this entity. *Acalculous cholecystitis* deserves special mention because it can result in significant morbidity and mortality for the ICU patient [20]. Although the signs and symptoms may be similar to those seen with calculous cholecystitis, the presentation in the postoperative or acutely ill ICU patient may be masked by the complicated underlying situation. In this setting, an aggressive diagnostic and therapeutic approach is essential because significant morbidity and even mortality continues to occur from complicated acalculous cholecystitis.

Supportive measures should be undertaken while the patient is being evaluated with noninvasive testing. Antibiotic therapy with broad-spectrum coverage should be initiated for patients with clinical evidence of sepsis, leukocytosis, or fever. Percutaneous cholecystostomy has become the therapy of choice for patients with acute calculous or acalculous cholecystitis who do not respond to conservative therapy and are too unstable for operative cholecystectomy. Percutaneous cholecystostomy is performed at the bedside using ultrasound guidance. A 22-gauge needle is inserted transhepatically into the gallbladder, and bile is aspirated. A guidewire is passed through this needle and the tract is dilated, allowing placement of a drainage catheter, with success rates exceeding 95%. Complications are few and include local wound infection, bleeding, and, rarely, bile peritonitis. The primary advantage of percutaneous cholecystostomy is that it can be done at the bedside without general anesthesia. Percutaneous cholecystostomy is often helpful for patients with suspected gallbladder disease, even if cholecystitis is not found, by excluding the diagnosis. Therefore, percutaneous cholecystostomy should be performed early if gallbladder disease is suspected. The cholecystostomy drainage catheter is left in place until acute symptoms resolve, at which time an elective surgical cholecystectomy or, in the setting of a patent cystic duct and functioning gallbladder, simple tube removal may be performed. For patients with acute calculous cholecystitis and severe underlying medical problems, the gallstones can be removed through the percutaneous tract using various techniques [21]. Such percutaneous gallstone removal is an effective
alternate therapy to cholecystectomy for patients with other significant medical conditions. Transpapillary drainage of the gallbladder at ERCP by nasocystic catheter or stent placement and EUS-guided gallbladder drainage via the transluminal route are two endoscopic options to treat patients with acute cholecystitis when standard treatment options fail or is contraindicated. It should be reserved for critically ill patients with severe comorbidities that preclude surgical cholecystectomy and/or patients with contraindications to placement of a percutaneous cholecystostomy tube in case of large-volume ascites, coagulopathy, or the presence of an intervening loop of bowel between the diaphragm and the liver that precludes percutaneous access [11].

Gallstone Pancreatitis

Gallstones are the most common cause of acute pancreatitis. Although most of the cases have an indolent course, about 25% of patients will develop clinically severe acute pancreatitis, usually because of necrotizing pancreatitis. There are several theories regarding the pathogenesis of gallstone pancreatitis, the most accepted being that stone passage or impaction in the ampulla is responsible for this entity. Gallstone pancreatitis should be considered and excluded during the evaluation of all patients with acute pancreatitis because it is a recurrent and treatable cause of this presentation. Standard abdominal ultrasound in combination with laboratory screening for biliary obstruction can be used to exclude gallstones as the cause for the pancreatitis for most patients [22]. Patients with acute pancreatitis should be classified into risk groups based on one of the accepted prognostic scales [23]. These scales include the Ranson criteria, the Glasgow criteria, the Acute Physiology and Chronic Health Evaluation IVa scoring system, and CT criteria for grading severity of pancreatitis. Grading by CT is based on the degree of inflammation, the presence of fluid collections, and the area of pancreatic necrosis seen during bolus infusion of intravenous contrast while scanning. These prognostic scales allow physicians to identify patients who are at risk of developing severe pancreatitis and a complicated hospital course.

Patients with acute pancreatitis from biliary stone disease should be managed initially as detailed in Chapter 209. Although most patients improve with conservative therapy alone, in patients who develop signs of worsening disease or biliary sepsis or coexisting cholangitis, early ERCP is strongly recommended, given the observed benefits in morbidity and mortality [11,24]. Early ERCP may also be beneficial for patients with persistent biliary obstruction (serum bilirubin > 2.5 mg per dL). Data are conflicting as to the benefit of early ERCP for patients with predicted severe disease in the absence of acute cholangitis. Early ERCP [25] allows
the removal of impacted or retained CBD stones, limiting further pancreatic inflammation and preventing cholangitis. Consultation with a skilled biliary endoscopist should be obtained early in the course for all patients with severe gallstone pancreatitis. The usual endoscopic approach at ERCP treatment is biliary sphincterotomy, even in the absence of overt stones on cholangiography. This is because small stones and sludge can be missed. In addition, sphincterotomy prevents recurrent pancreatitis in the interim to cholecystectomy, especially if cholecystectomy is not planned within the index admission because of advanced age or severe comorbid medical illnesses. An alternative to sphincterotomy for patients with coagulopathy is placement of a biliary stent to relieve jaundice and prevent stone impaction. Definitive therapy to prevent recurrent bouts may be accomplished by cholecystectomy or endoscopic sphincterotomy with stone extraction in nonoperative candidates. Although debate continues regarding the timing of surgery, it is generally accepted that all patients who are operative candidates should undergo cholecystectomy during the initial hospital admission after the pancreatitis has subsided [26]. Early operative intervention for patients with active severe gallstone pancreatitis has been associated with unacceptably high morbidity.

Summary

The management of biliary tract disorders encountered in the ICU varies with the specific disorder. Several of the evidence-based treatment approaches are listed in Table 208.2.

REFERENCES

15. Van Erpecum KJ: Complications of bile-duct stones: acute cholangitis

Pancreatitis is an inflammatory disease of the pancreas. It can be classified as *acute* or *chronic* based on clinical, morphologic, and functional criteria. The focus of this review is acute pancreatitis. *Acute pancreatitis* is defined as an inflammatory process that occurs in a gland that was morphologically and functionally normal before the attack and can return to that state after resolution of the attack.

The pathologic changes associated with acute pancreatitis vary to a great extent with the severity of the attack [1]. Nonsevere acute pancreatitis is associated with interstitial edema, a mild infiltration of inflammatory cells, and evidence of intrapancreatic or peripancreatic fat necrosis, or both. In contrast, severe acute pancreatitis is usually associated with acinar cell necrosis that may be either focal or diffuse. In addition, thrombosis of intrapancreatic vessels, vascular disruption with intraparenchymal hemorrhage, and abscess formation may be noted [2–5].
ETIOLOGY

Acute pancreatitis can be triggered by a number of etiologies [6–8]. In developed countries, acute pancreatitis is caused by ethanol abuse or biliary tract disease in 70% to 80% of patients. No etiology can be identified in another 10% to 20% of patients, a condition referred to as idiopathic pancreatitis. And a minority can be related to one of various etiologies listed in Table 209.1. In the less well-developed countries, particularly those in Africa and Asia, acute pancreatitis can develop as a result of malnutrition, ingestion of potentially toxic agents, or both; this type of acute pancreatitis has been called nutritional or tropical pancreatitis [9–12].

Biliary Tract Stone Disease

Biliary tract stone disease is an especially frequent cause of acute pancreatitis among American Indians of the Southwest, who are prone to development of stones, and among many Asian groups, who have a high incidence of stone formation as a consequence of chronic infection.

Reports by Acosta and Ledesma [13] and Acosta et al. [14] indicated that the onset of pancreatitis associated with biliary tract stones was related to the passage of stones through the terminal biliopancreatic duct and into the duodenum. The mechanism by which stone passage triggers this gallstone pancreatitis has been the subject of considerable speculation and experimental investigation. Three theories have been proposed. The first was the “common channel” theory proposed by Opie [15] in 1901 after he noted gallstones impacted the ampulla of Vater when patients dying of gallstone pancreatitis underwent autopsy examination. He suggested that such stones might create a common biliopancreatic channel proximal to the stone-induced obstruction and that, as a consequence, bile could reflux into the pancreatic ductal system. He reasoned that bile reflux would be injurious to the pancreas and trigger pancreatitis. Subsequent investigations by many groups, however, have challenged the validity of this theory pointing out that pancreatic duct pressure normally exceeds biliary duct pressure, and therefore pancreatic juice reflux into the biliary tract rather than bile reflux into the pancreas would be expected if an obstruction were to create a common channel [16]. Furthermore, many patients develop pancreatitis but lack a common channel that could permit reflux [17], and bile perfused into the pancreatic duct at normal pressure does not induce pancreatitis [18].

Another theory suggested that the stone passing through the sphincter of Oddi could render that sphincter incompetent and, as a result, permit reflux of duodenal juice containing activated digestive enzymes into the pancreas [19]. This “duodenal reflux” would seem to be an unlikely explanation for the development of pancreatitis because it is now clear that neither endoscopic nor surgical procedures that make the sphincter of Oddi incompetent lead to subsequent attacks of acute pancreatitis.

The third theory suggests that either the stone or edema and inflammation resulting from stone passage cause pancreatic duct obstruction and that pancreatic duct obstruction is the event that triggers acute pancreatitis. Studies using a model of acute necrotizing biliary pancreatitis induced in opossums support this theory [20], but in virtually all other species (dog, cat, mouse, rat, rabbit, etc.), pancreatic duct obstruction leads to atrophy of the pancreas with little or no evidence of pancreatitis. This observation has cast considerable doubt on the duct obstruction theory.

Uncertainty regarding mechanisms responsible for gallstone-induced
pancreatitis persists. It is generally believed that acute pancreatitis results from an autodigestive injury to the pancreas by enzymes that it normally synthesizes and secretes. Normally, those digestive enzymes are synthesized, intracellularly transported, and secreted from acinar cells as inactive zymogens. Activation normally occurs within the duodenum where the brush border enzyme enterokinase activates trypsinogen and trypsin activates the other zymogens. During pancreatitis, however, zymogen activation appears to occur inside acinar cells, perhaps as a result of pathologic changes in cytoplasmic calcium levels and colocalization of digestive zymogens with lysosomal hydrolases such as cathepsin B. Subsequently, zymogen activation leads to the acinar cell injury/death which is the hallmark of severe pancreatitis [21–25].

Ethanol Abuse

For most patients with ethanol-associated pancreatitis, their first clinical attack of pancreatitis develops after many years of ethanol abuse. The incidence of pancreatitis is related to the logarithm of alcohol consumption, but there is no threshold below which alcohol ingestion is not associated with an increased incidence of pancreatitis. The mean consumption of ethanol among patients with ethanol-associated pancreatitis is 150 to 175 g per day. The mean duration of consumption before the first attack is 18 ± 11 years for men and 11 ± 8 years for women [26]. Ethanol-associated pancreatitis, like ethanol abuse itself, is more common among men than among women. Epidemiologic studies suggested that ethanol-associated pancreatitis is most common among those ingesting a high-protein diet with either high or low fat content [26].

The mechanism by which ethanol might cause acute injury to the pancreas is not clear [27–29]. Direct toxic drug-like effect on acinar cells or induction of ductal hypertension as a result of stimulating exocrine secretion and sphincteric contraction are alternating theories [30,31]. Direct cellular injury may be mediated by ethanol metabolites [30–35], and circulating levels of bacterial endotoxin, perhaps released by the intestinal effects of ethanol, may be an important contributing event [34].

Genetic factors certainly predispose to pancreatitis in alcoholics [36,37]. One mechanism is via polymorphisms that may make the above processes more likely (such as increased permeability to endotoxins) and the other as independent pathways that increase susceptibility to mechanisms leading to pancreatic damage in alcoholics. A number of
genes have been implicated (SPINK1 [N34S], trypsinogen gene, CFTR); however, genetic testing is not necessarily clinically practical or available.

**Drugs**

Exposure to certain drugs represents perhaps the third most common cause of acute pancreatitis \[38–41\] (Table 209.2). The relationship between drug exposure and the development of pancreatitis can be categorized as definite, probable, or equivocal on the strength of the data that indicate that the drug actually causes pancreatitis. The former category includes those drugs whose use is associated with an increased incidence of pancreatitis and that, on specific rechallenge, have been found to induce the disease. On the contrary, drugs in the equivocal category include those that are anecdotally associated with the disease but never demonstrated in prospective studies to be capable of inducing pancreatitis. Historically, diuretic agents such as the thiazides, ethacrynic acid, and furosemide were considered the most likely drugs to cause pancreatitis. More recently, however, drug-related pancreatitis has been reported to be the most common among individuals with acquired immunodeficiency syndrome or acquired immunodeficiency syndrome–related complex receiving dideoxyinosine \[42\], pentamidine, or related compounds and among transplant patients receiving immunosuppressant agents such as azathioprine. Although previously considered to cause pancreatitis, histamine-2 (H$_2$)-blockers and steroids are not currently believed to be capable of causing acute pancreatitis.

Pancreatic Duct Obstruction

Obstruction of the pancreatic duct may be caused by duodenal, ampullary, biliary duct, or pancreatic tumors or by inflammatory lesions (e.g., peptic ulcer, duodenal Crohn disease, periampullary diverticulitis) that interfere with pancreatic duct drainage [6]. Pancreatic cysts and pseudocysts and periampullary diverticula filled with food and debris can interfere with duct drainage and as a consequence precipitate pancreatitis. Ductal strictures, frequently the result of traumatic duct injury or previous pancreatitis, can be a cause for obstructive pancreatitis. Finally, certain parasites, such as Ascaris and Clonorchis, can trigger pancreatitis by physically obstructing the pancreatic duct [6,43]. An association between pancreas divisum and pancreatitis has been claimed, presumably reflecting relative obstruction to pancreatic juice flow at the lesser papilla [44], but this is quite controversial [45,46].

Other Miscellaneous Causes of Acute Pancreatitis

Many of the remaining miscellaneous causes of pancreatitis are listed in Table 209.1. Traumatic pancreatitis usually follows blunt abdominal trauma, during which the body of the pancreas is compressed against the vertebral column. As a result, the gland is “cracked,” and the duct is either partially or completely transected [47]. Lesser degrees of blunt trauma may be associated with pancreatic contusion, whereas penetrating injury can affect any portion of the pancreas. Traumatic injury to the pancreas can also be associated with surgical procedures performed on or near the pancreas [48–50]. Postoperative pancreatitis is also frequently associated with procedures performed on or near the sphincter of Oddi (duct exploration, sphincteroplasty, and distal gastrectomy), procedures associated with hypoperfusion or atheroembolism of the pancreatic circulation (cardiopulmonary bypass, cardiac transplantation, renal transplantation, and translumbar aortography) [51,52], or procedures involving pancreatic duct injection (endoscopic retrograde cholangiopancreatography [ERCP]) [53].

Hereditary pancreatitis, a familial disease transmitted by a mutation on chromosome 7 that is transmitted as autosomal dominant with incomplete penetrance, can also cause acute pancreatitis among a minority of patients [54]. Reports indicate that the mutation results in
the synthesis of a cationic trypsinogen that is resistant to autoinactivation after activation has occurred [55]. Patients with classic cystic fibrosis mutations can present with pancreatitis even in the absence of pulmonary disease. Studies indicate that a substantial number of patients with the so-called idiopathic pancreatitis may have nonclassical cystic fibrosis mutations or polymorphisms of CFTR [56]. The significance of hereditary pancreatitis is the high incidence of pancreatic cancer among this group of patients, which warrants surveillance.

A number of recent reports, particularly from Japan, have drawn attention to a form of autoimmune pancreatitis characterized by extensive lymphoplasmacytic infiltration into the pancreas and sclerosis of the pancreatic and bile ducts. Patients with this form of pancreatitis frequently present with both bile and pancreatic duct obstruction and a mass in the head of the pancreas. They can easily be thought to have neoplastic disease of the pancreas but, if placed on steroid treatment, the changes of autoimmune pancreatitis rapidly resolve. Many, but not all, of these patients have elevated circulating levels of immunoglobulin G (IgG4), and this may permit their identification [57].

**Idiopathic Pancreatitis**

Approximately 5% to 10% of patients with acute pancreatitis have the disease in the absence of any identifiable etiology. Reports suggest that many of these patients have biliary sludge, that their attacks can be prevented by cholecystectomy, and that they actually have biliary rather than idiopathic pancreatitis [58,59].
CLINICAL PRESENTATION

Symptoms

The symptoms of acute pancreatitis include abdominal pain, nausea, and vomiting [6,7,43,60,61] (Table 209.3). The pain typically is localized to the epigastrium but frequently involves one or both upper quadrants. On occasion, it may be felt in the lower abdomen, one or both shoulders, or the lower chest. The pain is usually described as being of rapid onset, slowly increasing to a maximal severity, and then remaining constant. It usually lacks the waxing and waning character of intestinal or ureteral colic, but it may be diminished by assuming an upright position, leaning forward, or lying on the side with the knees drawn upward. The pain may have a pleuritic component and may be associated with rapid but shallow respirations. Frequently, the pain is described as being a boring or knifelike sensation that passes straight through to the midcentral back from the epigastrium.

Nausea and vomiting commonly are noted among patients with acute pancreatitis. The vomiting typically persists even after the stomach has been emptied and may result in gastroesophageal tears with bleeding (i.e., Mallory–Weiss syndrome). The vomiting and retching may be relieved by passage of a nasogastric tube, but neither the vomiting nor gastric decompression results in reduction of the abdominal pain.

Physical Examination
Patients with acute pancreatitis typically appear anxious and ill. They may be diaphoretic and hyperthermic. Tachycardia, tachypnea, and hypotension are common. Patients often roll or move around in search of a more comfortable position. In this respect, they are quite unlike those with peritonitis caused by a perforated viscus, which remain motionless because movement exacerbates their pain. Most patients with acute pancreatitis have a clear sensorium, but some have mild or even severe alterations in their mental status as a result of drug or ethanol exposure, hypoxemia, hypotension, or release of circulating toxic agents from the inflamed pancreas. Jaundice is common, even in patients with nonbiliary pancreatitis, among whom the hyperbilirubinemia may reflect nonobstructive cholestasis.

The abdominal examination of patients with acute pancreatitis usually reveals abdominal tenderness and voluntary and involuntary guarding. These findings may be limited to the epigastrium or diffusely present throughout the abdomen. A mass, located in the epigastrium or left upper quadrant of the abdomen, or both, may be felt. Direct, percussion, and rebound tenderness usually can be elicited. Abdominal distention also can be seen. Hypovolemia and dehydration are commonly present and can be detected by the presence of hypotension, tachycardia, collapsed neck veins, dry skin, dry mucous membranes, and decreased turgor. Bowel sounds are often diminished or absent. Flank ecchymoses (Grey Turner sign) or other evidence of retroperitoneal bleeding (Cullen sign) may be noted. Examination of the chest may reveal evidence of pleural effusion that may be on either or both sides but is most commonly present on the left. Because of pleuritic and abdominal pain, deep breathing is difficult, and atelectasis, particularly at the bases, is common. Examination of the skin may reveal areas of tender subcutaneous induration and erythema that resemble erythema nodosum; these lesions are believed to result from fat digestion by circulating pancreatic lipases.
Acute pancreatitis is associated with significant losses of intravascular fluid. A substantial amount of fluid is lost as a result of the anorexia, nausea, and vomiting that accompanies the disease. In addition to these fluid losses, large volumes of fluid can be sequestered in the retroperitoneum as a result of the pancreatic inflammatory process. In addition, a systemic “capillary leak” process may result in additional fluid sequestration. Taken together, these losses of fluid from the intravascular compartment can cause the hemoglobin, hematocrit, blood urea nitrogen, and serum creatinine to rise. Hypoalbuminemia is common, but the serum electrolytes may remain normal unless vomiting has been significant. Because of the pancreatic inflammatory process, the white blood cell count usually is elevated and the differential may show a “left shift” (neutrophilic predominance). Hyperglycemia, which commonly is noted, may result from the combined effects of elevated circulating catecholamines, decreased insulin release, and hyperglucagonemia [62,63]. A mild rise in serum bilirubin from nonobstructive cholestasis frequently is seen even with nonbiliary acute pancreatitis. When the disease is induced by the passage of gallstones, the hyperbilirubinemia is even more marked, and superimposed cholangitis with bacteremia and positive blood cultures can occur [64]. Markedly elevated circulating triglyceride levels always are seen in individuals whose pancreatitis is caused by hyperlipoproteinemia [65], but hypertriglyceridemia with lactescent serum also can be seen in alcohol-induced acute pancreatitis [66].

Hypocalcemia is relatively common among individuals with acute pancreatitis [67]. For the most part, the hypocalcemia is caused by hypoalbuminemia, and as a result, the ionized calcium level is actually normal. For some patients, however, hypocalcemia can develop that is out of proportion to the degree of hypoalbuminemia and that reflects a true decrease in circulating ionized calcium levels. Tetany and carpopedal spasm and other complications of their hypocalcemia may develop among these patients. Marked hypocalcemia has been considered to be a sign of a poor prognosis. In patients with severe pancreatitis, disseminated intravascular coagulation may develop [68], and as a result, they may have thrombocytopenia, elevated levels of fibrin degradation products, decreased fibrinogen levels, and prolongations of the partial
thromboplastin and prothrombin times.

Pancreatic Enzymes and Other Assays

The serum amylase concentration is usually, but not always, elevated during an attack of pancreatitis [7]. The magnitude of that rise does not depend on the severity of pancreatitis, and some reports indicate that as many as 10% of patients with lethal pancreatitis have normal or near-normal serum amylase levels [69]. To a great extent, this may reflect the fact that amylase elevations during pancreatitis typically are transient, with an increase 2 to 12 hours after the onset of an attack and a decline in serum amylase values to near-normal levels 3 to 6 days after the attack has begun. Thus, patients presenting long after the onset of an attack may have normal or only slightly increased serum amylase levels.

Serum amylase activity also may be increased in a number of diseases other than pancreatitis [7,61,70]. Amylase may be synthesized at extrapancreatic sites (e.g., salivary glands, fallopian tube, and lung) or produced by nonpancreatic tumors (e.g., lung, prostate, and ovary), and release of the nonpancreatic amylase into the circulation may result in hyperamylasemia (Table 209.4). Patients with these nonpancreatic extra-abdominal causes for hyperamylasemia rarely are confused with those who have pancreatitis because the clinical features of pancreatitis are usually absent in the former group. On the contrary, some patients with disorders that might be clinically confused with acute pancreatitis may also have hyperamylasemia. This is particularly true for patients with acute cholecystitis, perforated gastric or duodenal ulcers, small bowel obstruction, intestinal ischemia, and intestinal infarction. It may also be true for some patients passing common bile duct stones into the duodenum who do not have pancreatitis.

The overall sensitivity and specificity of amylase determination for the diagnosis of pancreatitis depends on the value chosen as the cutoff level [71] and the presence or absence of clinical features of pancreatitis. Patients with hyperamylasemia but not pancreatitis usually have mild elevations of the circulating amylase level (approximately 200 IU per L) or lack clinical features of pancreatitis, or both, whereas those with pancreatitis usually manifest profound hyperamylasemia (>1,000 IU per L) in association with clinical features of the disease.

Approximately 0.5% of individuals have a condition referred to as macroamylasemia in which amylase is bound to an abnormal circulating protein and, as a result, the amylase is not cleared by the kidney [61,72,73]. Some of these individuals may develop abdominal pain and may be incorrectly suspected of having pancreatitis. In this setting, measurement of urinary amylase activity may be particularly helpful because, in macroamylasemia, urinary amylase levels are usually very low. On the other hand, urinary amylase activity may be particularly helpful for patients who are first seen several days after an attack of pancreatitis and who are found to have normal or near-normal serum amylase activity [63], because urinary amylase level may remain elevated long after serum levels have normalized. Renal clearance of amylase also may be reduced as a result of renal failure, and this reduced clearance can lead to mild hyperamylasemia. On the contrary, enhanced renal clearance of amylase can occur in pancreatitis, and this phenomenon can result in an increase in the clearance ratio for amylase compared with creatinine [73,74]. However, measurement of the so-called amylase to creatinine clearance ratio has not been helpful for the diagnosis of pancreatitis. Alterations of this ratio appear to represent a nonspecific response to an acute illness. Thus, the clearance ratio may be elevated for many patients who lack pancreatitis but may be normal in many who have pancreatitis [72–78].

Serum lipase level is commonly checked as part of the assessment for
acute pancreatitis. In an acute attack, levels can rise within 4 to 8 hours, peak by 24 hours, and remain elevated for up to 14 days (prolonged elevation of serum lipase may be suggestive of a cyst formation); and for this reason, serum lipase may be the more useful test than serum amylase when evaluating a patient for pancreatitis more than 24 hours after onset of symptoms. Similar to amylase levels, hyperlipasemia may be seen in a number of other diseases, including renal disease, liver cirrhosis, alcohol abuse, small bowel obstruction, acute cholecystitis, peptic ulcer disease, and intestinal infarction. Based on the assays used by different studies, specificity and sensitivity can vary, 42% to 100% and 56% to 100%, respectively. Studies using a higher cutoff to correlate with a diagnosis of acute pancreatitis report a higher specificity at the cost of sensitivity [79]. Although measurements of both enzymes have been used for diagnosing pancreatitis, because of issues involving costs and other factors, most practices will often utilize one of these as the primary assay (studies show that measurements of both enzymes do not increase the accuracy of the diagnosis). Studies using receiver operator characteristics curves show that serum lipase levels gave the greater diagnostic accuracy compared to amylase [80]. The American College of Gastroenterology Guidelines on management of acute pancreatitis recommend clinical correlation with symptoms and presentation when evaluating elevated levels or either enzyme [81].

Circulating levels of other pancreatic enzymes (trypsinogen, chymotrypsinogen, phospholipase, and elastase) or urinary levels of the activation peptide released when trypsinogen is activated (i.e., trypsinogen activation peptide) can also be measured, but there is little or no evidence to suggest that these determinations are more helpful in the diagnosis of pancreatitis than the simpler measurement of serum amylase activity [69,82,83]. Acute pancreatitis also can be associated with methemalbuminemia [84] and with increased circulating levels of several cytokines (e.g., interleukin-1 [IL-1], IL-6, and tumor necrosis factor-α) [85] and acute-phase reactants (e.g., C-reactive protein) [86,87]. The magnitude and duration of these changes may have some prognostic value in pancreatitis, but these changes are not specific to pancreatitis and are therefore of little diagnostic value.

Ultrasonography

Ultrasonography for patients with acute pancreatitis is helpful for detecting gallbladder stones, bile duct dilatation, or both [88]. Endoscopic ultrasound (EUS) can help with investigation of the biliary
Computed Tomography

For acute pancreatitis, particularly during the early stages of the disease, computed tomography (CT) is the most useful imaging modality because it can define the gross features of the pancreas and peripancreatic organs without being limited by the presence of distended gas-filled loops of bowel in the upper abdomen [89]. It is not needed for the diagnosis of the condition, but it should be used if the diagnosis is not clear. The pancreas may be normal or slightly swollen in appearance on CT in mild cases of pancreatitis. Evidence of peripancreatic inflammation, including streaking in the retroperitoneal and transverse mesocolic fat, may also be seen. With more severe attacks, peripancreatic and intrapancreatic fluid collections can be detected. Dynamic CT, performed by rapidly imaging the pancreas during bolus injection of contrast material, can define areas of pancreatic necrosis because those areas do not enhance as a result of contrast administration [90–92]. Detection of these changes may be of prognostic value in acute pancreatitis [93] (see “Prognosis” section), but their major value in the early stages of the disease lies in the fact that their presence confirms the diagnosis of acute pancreatitis. Conversely, the finding of a normal pancreas without signs of peripancreatic inflammation on the CT of a patient suspected of having severe pancreatitis, particularly if that patient’s condition is deteriorating, should suggest that the patient does not have pancreatitis.

MRI can also be of great value in the diagnosis of acute pancreatitis. It can reveal the presence of an inciting stone in the distal bile duct. In addition, MRI may be more accurate than CT in defining the extent of pancreatitis-associated necrosis [94].
DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute pancreatitis includes other processes that may cause upper abdominal pain, nausea, vomiting, and abdominal tenderness. The serum amylase or lipase, or both, is usually elevated in acute pancreatitis and normal or near normal in many other processes that may cause similar symptoms. On the contrary, serum levels of pancreatic enzymes may be elevated with some states that can mimic acute pancreatitis (Table 209.5). On occasion, however, the diagnosis may be uncertain, and CT scan may be helpful.

PROGNOSIS

The management of patients with acute pancreatitis will depend on the severity of their condition. A number of clinical features have been identified that are associated with a poor prognosis. These include age older than 60 years, a “first attack” of pancreatitis, obesity, postoperative pancreatitis, hypocalcemia, methemalbuminemia, and the presence of either Grey Turner or Cullen sign [95]. However, the most common methods for evaluating the severity of acute pancreatitis are Ranson criteria [96] and Imrie criteria [97] as listed in Tables 209.6 and 209.7, respectively. The presence of fewer than three of the Ranson criteria is associated with mild pancreatitis, little morbidity, and a mortality of less than 1%. In contrast, many patients with three or more of these prognostic signs have severe pancreatitis, with a 34% incidence of septic complications and a mortality that, with seven to eight prognostic signs, may reach 90%. Using the Imrie criteria, severe pancreatitis has been found when three or more of the criteria are present, whereas mild pancreatitis is associated with fewer of the prognostic signs.

Although the criteria developed by the New York and Glasgow groups have proved to be of considerable value in allowing prospective trials in the evaluation of new therapies and interventions for acute pancreatitis, these prognostic criteria are not particularly helpful for the management of an individual patient and should never be used as criteria for the diagnosis of pancreatitis. The Acute Physiology and Chronic Health Evaluation-IV (APACHE-IV) system [98] has been well studied and validated for its ability to predict mortality in patients with acute pancreatitis, with most guidelines recommending a cutoff score of 8 (at admission) above which severe disease is predicted. A newer scoring system, Bedside Index of Severity in Acute Pancreatitis, has been shown to have similar accuracy to the APACHE-2 system with the benefit of being easier to calculate. A cutoff score of 3 during the earlier phase of the disease identifies patients with an increased risk of death [99].

If a CT scan is obtained, the severity of the pancreatitis can be evaluated based on the Balthazar score [100], in a prospective study involving 83 patients with acute pancreatitis, noted that those with two or more peripancreatic fluid collections seen on CT had a 61% incidence of late pancreatic abscess, those with only one fluid collection or inflammation confined to the pancreas and peripancreatic fat had a 12% to 17% incidence of pancreatic abscess, and those with either no CT changes of pancreatitis or with only pancreatic enlargement on CT had a zero incidence of pancreatic abscess. The morbidity, incidence of abscess formation, and mortality for an attack of pancreatitis also have been shown to be related to the amount of pancreatic tissue that is not enhanced on CT after bolus administration of contrast material during dynamic CT. In addition to these scoring systems, other factors characterizing acute pancreatitis may be helpful for predicting the severity and, thus, the outcome after an attack. Most notable in this regard are the presence or onset, shortly after presentation, of evidence suggesting organ failure and/or evidence of extravascular extravasation of normally intravascular fluid [7,101,102]. This fluid loss can result in
renal failure, respiratory failure, or both as well as hemoconcentration, and each of these changes is predictive of a poor outcome. In contrast, the absence of hemoconcentration on admission usually suggests that pancreatic necrosis is unlikely [103,104]. Elevated circulating levels of other factors (e.g., C-reactive protein, certain cytokines, phospholipase A2, trypsinogen activation peptide, and trypsinogen-2) are also suggestive of a severe attack and predictive of poor outcomes [7].
TREATMENT OF ACUTE PANCREATITIS

Initial Management
During the early stages of an acute attack of pancreatitis, efforts should be made to confirm the diagnosis, control pain, and support fluid and electrolyte needs [105].

Treatment of Pain
The pain of pancreatitis is often severe and difficult to control. Most patients require narcotic medications. In clinical practice, narcotics available on inpatient pharmacy formulary plans are used often via a patient controlled administration pump [37].

Fluid and Electrolyte Replacement
The early stage of severe acute pancreatitis is characterized by major fluid and electrolyte losses. External losses, caused by repeated episodes of vomiting and exacerbated by nausea and diminished fluid intake, can lead to hypochloremic alkalosis. Internal losses caused by leakage of intravascular fluid into the inflamed retroperitoneum, pulmonary parenchyma, and soft tissues elsewhere in the body contribute to hypovolemia. Aggressive and adequate fluid resuscitation, instituted during the early stages of acute pancreatitis, is essential. A growing body of evidence indicates that inadequate fluid resuscitation may promote progression of otherwise mild pancreatitis into severe pancreatitis, with its associated major morbidity and high mortality. Recently, studies have suggested the use of ringer's lactate solution rather than saline to neutralize the development of metabolic acidosis.

Nutrition
Nutrition is the other most important arm of therapy for patients with severe acute pancreatitis. If provided enterally, it can feed the gut and decrease ischemia and transmigration of organisms into areas of necrosis with improved patient outcomes. A number of studies have demonstrated the benefits of nasojejunal tube feedings that support these contentions [106,107]. Furthermore, recent reports suggest that enteral nutrition can be successfully administered by either the nasogastric or the nasojejunal route and that the benefits of using either route are comparable.
Other Treatments

Recommendations for the use of antimicrobial agents have changed over time. Current guidelines published by the American College of Gastroenterology, based on a number of studies, recommend against prophylactic antibiotics or antifungals, even in cases of severe pancreatitis (strong recommendation with moderate level of evidence quoted). Concomitant infections (such as cholangitis or pneumonia) should be treated appropriately [81]. A summary of treatments of little or unproven value is presented in Table 209.8 and management recommendations for acute pancreatitis are presented in Table 209.9.

TABLE 209.9 Complications of Acute Pancreatitis

Systemic complications
- Cardiovascular collapse
- Respiratory failure
- Renal failure
- Metabolic encephalopathy
- Disseminated intravascular coagulation
- Gastrointestinal bleeding

Local complications
- Acute fluid collection
- Pancreatic necrosis ± infection
- Pancreatic pseudocyst
- Pancreatic abscess
- Pancreatic ascites
- Pancreatic-pleural fistula
- Duodenal obstruction
- Bile duct obstruction
- Splenic vein thrombosis
- Pseudoaneurysm + hemorrhage

Role of Surgery and Endoscopy for Gallstone Pancreatitis

Most patients with biliary tract stone-induced pancreatitis recover quickly and uneventfully because the offending stone is either passed into the duodenum or disimpacts itself from the ampulla of Vater by moving proximally in the duct. The role of early ERCP is well established in cases of severe gallstone pancreatitis. Three prospectively randomized controlled trials and a recent observational, prospective, multicenter trial have evaluated the benefit of early endoscopic sphincterotomy and stone extraction in the management of patients with gallstone pancreatitis [64,110–112]. Each study concluded that early intervention did not alter the course of mild pancreatitis, but they suggested [64,110,112] that the morbidity of severe pancreatitis, particularly if it was associated with cholestasis, was reduced by early stone removal. Therefore, on the basis
of currently available data, it seems most appropriate that patients with mild pancreatitis need not undergo either early surgical or endoscopic intervention. On the contrary, early intervention by ERCP seems warranted for patients with severe gallstone pancreatitis.

Recurrent attacks of gallstone pancreatitis may develop if stones either in the gallbladder or biliary ducts remain after resolution of the index attack. For that reason, most clinicians recommend that some form of treatment designed to prevent recurrent attacks should be administered before discharge of the patient from the hospital [106]. That might be accomplished by laparoscopic or open cholecystectomy combined with surgical or endoscopic duct clearance if choledocholithiasis is discovered by preoperative magnetic resonance cholangiopancreatography. Alternatively, for patients whose only symptoms are those of ductal disease and who lack symptoms of cholecystolithiasis, endoscopic sphincterotomy and duct clearance may be sufficient, particularly if those patients have high surgical risks.

**Treatment of Systemic Complications**

Systemic complications of acute pancreatitis include cardiovascular collapse, respiratory failure, renal failure, metabolic encephalopathy, disseminated intravascular coagulation, and gastrointestinal bleeding (Table 209.10). For the most part, the pathogenesis and management of these manifestations of acute pancreatitis are identical to those involved when these processes are superimposed on other diseases that result in severe peritonitis and hypovolemic shock. In other words, there may be nothing specific about these systemic complications of pancreatitis, although they may be worsened by circulating vasoactive agents, activated digestive enzymes, and protein breakdown fragments absorbed from the inflamed pancreas. Please refer to the chapters on peritonitis in chapter 51 and management of shock in chapter 37 for the detailed management of these problems.

**TABLE 209.10 Summary of Management of Acute Pancreatitis**

- Early, aggressive fluid resuscitation is beneficial in cases of severe acute pancreatitis associated with shock [114].
- In contrast to morphine, meperidine relaxes the sphincter of Oddi and is thus a favored analgesic in cases of pancreatitis [115,116].
- Use of enteral nutrition has shown benefit over parenteral nutrition in terms of duration of hospital stay,
infectious morbidity, and need for surgery in meta-analysis [117–119]. Enteral nutrition, because it is associated with fewer complications, may be the better of these two treatment modalities.

- Antibiotic use remains controversial; meta-analyses have shown utility in preventing infection of pancreatic necrosis [120,121], although a large, randomized, controlled trial failed to demonstrate benefit [122].

- In cases of severe necrotizing pancreatitis, conservative management in an intensive care setting trends toward a survival benefit when compared with early surgical intervention [123].

- Early endoscopic sphincterotomy and stone extraction are beneficial in preventing sepsis in cases of severe gallstone pancreatitis in patients with jaundice [64,110,124].
LOCAL COMPLICATIONS OF PANCREATITIS

Definitions

Considerable confusion has surrounded the terminology used to describe the local complications of an acute attack of pancreatitis. At a symposium in Atlanta, an international group of clinicians and scientists attempted to resolve this confusion by proposing the use of the following definitions [113]:

1. *Acute pancreatic and peripancreatic fluid collections*: Fluid collections in or near the pancreas that occur early in the course of acute pancreatitis and that lack a wall of granulation or fibrous tissue.

2. *Pancreatic necrosis*: An area of nonviable pancreatic tissue that may be diffuse or focal and that typically is associated with peripancreatic fat necrosis. Pancreatic necrosis may be either *sterile* or *infected*.

3. *Pancreatic pseudocyst*: A collection of pancreatic juice that usually is rich in digestive enzymes and that is enclosed by a nonepithelialized wall of fibrous or granulation tissue (Figs. 209.1 and 209.2). It is usually round or ovoid in shape and not present until 4 to 6 weeks have elapsed from the onset of acute pancreatitis. Before this time, the fluid collection usually lacks a defined wall and may be either an *acute fluid collection* or a localized area of *pancreatic necrosis*. Bacteria may be present in a pseudocyst as a result of contamination; but in this setting, clinical signs of infection usually are absent. When pus is present, however, the lesion should be referred to as a *pancreatic abscess*. Leakage of pseudocysts into the peritoneal cavity or chest leads to the development of *pancreatic ascites* or *pancreatic-pleural fistula*, respectively.
FIGURE 209.1 Ultrasound showing pancreatic pseudocyst (arrows).

FIGURE 209.2 Computed tomography showing
pseudocyst (arrows) in the head of the pancreas.

4. **Pancreatic abscess**: A circumscribed intra-abdominal collection of pus, usually in proximity to the pancreas, which contains little or no pancreatic necrosis that arises as a consequence of either acute pancreatitis or pancreatic trauma (Fig. 209.3). The relative absence of necrosis distinguishes *pancreatic abscess* from *infected pancreatic necrosis*.

![Computed tomography showing gas-filled pancreatic abscess (arrows).](image)

5. **Walled-off Pancreatic Necrosis (WOPN)**: Also called organized pancreatic necrosis, the term walled-off pancreatic necrosis was first introduced in 2005. It is characterized by granulation tissue forming around a collection of enzymes and debris and even bacteria (which can in fact secondarily seed the collection).

**Diagnosis**

These types of fluid collections are usually found as a complication of severe acute pancreatitis 7 to 10 days following the onset of symptoms. Usually, patients seem to develop recurrence of their pain in association with fever and leukocytosis.

Dynamic contrast-enhanced CT and MRI are the most accurate means of identifying these complications of acute pancreatitis. The presence of extra-intestinal gas on CT is diagnostic of either infected necrosis or abscess, but this finding is only occasionally noted. More often, patients with either infected necrosis or abscess are found to have poorly
enhanced areas on dynamic CT in a clinical setting of suspected sepsis. When doubt about the presence or absence of infection persists, fine-needle aspiration of these areas, under CT or EUS guidance, may yield material that, on Gram stain, reveals the presence of a pathogenic microorganism [125,126].

Management

Acute Fluid Collections

Acute fluid collections generally require no specific treatment. They usually resolve spontaneously within several weeks of an attack. Attempts to drain these collections either by percutaneously placed catheters or by early surgical intervention should be discouraged.

Sterile Necrosis

Patients with sterile necrosis, even if extensive, should be managed nonoperatively during the initial few weeks of their illness [127]. Surgical intervention in such patients may be associated with considerable morbidity and may even result in secondary infection of the inflamed, but previously sterile, pancreas. Although the consensus view is that patients with sterile necrosis do not need intervention during the early phases of their disease, the potential value of intervention at later times is not entirely clear. Some of these patients experience a very prolonged illness, and full recovery may only be possible after the devitalized pancreatic and peripancreatic tissue has been removed. This can be accomplished surgically by exposing the involved area and removing the necrotic tissue—a procedure that may require repeated operations and can lead to considerable morbidity. Alternatives to this approach have been proposed. They involve transpapillary or transcutaneous placement of irrigating catheters into the involved area followed by debridement achieved by continuous lavage [128–130]. In another approach, debridement is achieved using a percutaneously placed operating nephroscope or laparoscope [131,132]. A more common approach is an endoscopic necrosectomy [133]. Often, unless there is evidence of infected necrosis, an endoscopic necrosectomy is planned for a 4 to 6 weeks after the resolution of the acute episode, allowing for the necrosis to wall off. Even at this time, necrosectomy is often indicated based on symptoms and after further radiologic assessment. It is not uncommon for multiple procedures to be performed over several weeks in order to achieve resolution of the necrosis. Although there have been no randomized controlled trials comparing endoscopic necrosectomy with surgical necrosectomy, the benefits of the
former outweigh the morbidity associated with open necrosectomy, and often is the preferred approach for addressing persistent pancreatic necrosis.

Infected Necrosis

Infected necrosis is usually an indication for surgical intervention in symptomatic patients, whether it is detected by the presence of extra-intestinal gas on CT examination or by fine-needle aspiration of an area of pancreatic necrosis. However, more recently endoscopic necrosectomy seems to have also been useful as a less invasive approach. Organisms recovered in areas of infected pancreatic necrosis usually are those that are present in the gastrointestinal tract (Klebsiella spp, Pseudomonas spp, Escherichia coli, Enterococcus, Proteus spp) [134]. In addition, yeast such as Candida albicans may be encountered. It is believed that most of these organisms reach the inflamed pancreas via transmigration from adjacent segments of the intestine. Antibiotic therapy, although indicated, by itself usually represents an inadequate approach to the management of infected pancreatic necrosis. If the endoscopic approach is unsuccessful, surgical debridement and drainage should be considered. This is especially true for the unstable or septic patient who is doing poorly with nonoperative management.

Recent reports have suggested that stable patients with infected necrosis can be managed more electively and conservatively, particularly those stable patients who are asymptomatic; delay in performing surgical debridement may actually be beneficial because it appears to improve survival, decrease surgical complications, and decrease the need for repeated operations when compared with early operation for this group [135]. Furthermore, although most of these patients will eventually need debridement, recent anecdotal reports have indicated that some may be definitively treated with either antibiotics alone or with antibiotics combined with percutaneous drainage [136].

Pseudocyst

Pseudocysts may cause symptoms either because they are themselves tender or because they result in obstruction of adjacent organs such as the stomach, duodenum, and bile duct. On the other hand, many pseudocysts do not cause symptoms. Only symptomatic pseudocysts need to be treated [137–139].

Several methods of treating pseudocysts have been proposed, including
either open or laparoscopic internal surgical drainage (cystogastrostomy, cystoduodenostomy, and Roux-en-Y cystojejunostomy), endoscopic drainage (cystogastrostomy, cystoduodenostomy), and percutaneous drainage (aspiration, aspiration followed by administration of somatostatin, and catheter drainage, with or without administration of somatostatin) [140]. Percutaneous drainage has a considerable incidence of either recurrence after aspiration or infection after catheter drainage. On the other hand, endoscopic drainage, via endoscopic cystoduodenostomy or cystogastrostomy, is a highly effective way of managing cysts located in the pancreatic head or body, particularly if they are pressing inward on the duodenum or stomach and there is little in the way of tissue or blood vessels interposed between the cyst and the duodenal or gastric lumen [141]. Surgical internal drainage (i.e., cystojejunostomy, cystogastrostomy) would seem most appropriate for management of cysts in the pancreatic tail or the head/body cysts that cannot be safely accessed endoscopically.

Pancreatic Ascites and Pancreatic Duct Fistulas

Patients with pancreatic ascites or pancreatic-pleural fistulas may respond to nonoperative therapy with bowel rest, parenteral nutrition, and administration of somatostatin or other agents designed to inhibit pancreatic secretion [142–149]. Most, however, fail this method of treatment, and some form of intervention is needed. An ERCP should be performed to identify the site of ductal disruption [150–152] that, if in the pancreatic tail, can be treated easily by distal pancreatectomy. Alternatively, anastomosis of a Roux-en-Y loop of jejunum to the site of rupture, particularly if it is in the head or neck of the gland, may be preferable. Endoscopically placed stents also can be used to prevent leakage of juice from the duct, and this nonoperative approach can be useful in the management of these complications [153].
Historically, the curative and first-line treatment for WOPN has been surgical debridement. Alternatively, laparoscopic drainage has been used for patients in whom surgery is deemed too risky a procedure. Both approaches have drawbacks. Often, patients may need more than one operation for complete debridement and can develop abdominal wall hernia as well as external fistulae. And laparoscopic drainage often yields less than complete drainage of the necrotic material. Recent advancements with endoscopic interventions however support EUS-guided or direct endoscopic, transgastric, or transduodenal necrosectomy as an equally effective therapy. Reports suggest that cure rates are similar to those with surgical therapy, approaching 91% at approximately 5 months (with repeat procedures in this time frame). Serious major complications include major bleeding and perforation, and other adverse events may be a function of severity of disease and comorbidities [154].
CONCLUSIONS

The knowledge base for acute pancreatitis has changed dramatically in the past decade. Understanding of the genetic basis of the disease, approaching its management, and the use of less invasive methods of management is currently accepted practice. However, a number of questions still remain: rate of fluid resuscitation, types of fluids to use, and role of oral feedings. It is not until these issues are clearly addressed through clinical trials that we can identify the best way to care of these complicated patients and to develop an acute pancreatitis quality index for the proper care and management of these patients.
ACKNOWLEDGMENT

We thank Dr. Michael Steer for his many contributions to this chapter.

Diarrhea frequently complicates the course of the critically ill patient, occurring in 40% to 50% of patients in the intensive care unit (ICU). Diarrhea is the most common nonhemorrhagic gastrointestinal (GI) complication in this patient population [1–3]. Despite its high prevalence among the ICU patient population, diarrhea is frequently overlooked by physicians and the ICU team, especially when more emergent cardiovascular, respiratory, and infectious issues are present. Inattention to excessive stool output, however, can often result in serious perturbations of fluid and electrolyte balance, promote skin breakdown and infection, and create difficulty in the administration of proper nutritional support. In these instances, proper and immediate evaluation and management are essential to prevent further complications in a critically ill patient. The evaluation of diarrhea is often limited by the patient’s status and practical limitations in performing diagnostic studies in the ICU setting.

The term diarrhea often carries a different meaning for patients and health care providers. Increases in stool frequency or fluidity do not necessarily indicate the presence of diarrhea. In a general patient population, an increase in daily stool weight or volume (exceeding 200 g per day) has been used as an objective-defining criterion [4]. In the critically ill patient, however, accurate measurement of stool output may be difficult, if not impossible. Physicians, therefore, must use their best judgment to decide whether diarrhea is present and to determine whether it represents a clinical problem requiring attention. This chapter provides helpful insights for making these decisions, presents guidelines for rapid and directed evaluation, and suggests effective approaches for the management of diarrhea in this setting.
ETIOLOGY

The causative factors of diarrhea in the ICU patient differ considerably from those in the general population. Numerous causes of diarrhea in the ICU setting exist and can be broadly divided into three categories: (a) diarrhea secondary to iatrogenic causes, (b) diarrhea secondary to underlying diseases, and (c) diarrhea resulting as a primary manifestation of specific diseases. Careful review of clinical information will allow physicians to narrow the diagnostic possibilities and avoid overlooking simple and common causes of diarrhea (Table 210.1). In some patients, diarrhea is the result of a combination of factors. Thus, it is incumbent on the physician to carefully review available data to identify the cause(s) of diarrhea.

Iatrogenic Causes

Iatrogenic factors are the most commonly and frequently overlooked cause of diarrhea in the critically ill patient. Furthermore, rapid and successful treatment of iatrogenic diarrhea can often be achieved by eliminating the offending agent or process.

Medications

Medications are a frequent cause of iatrogenic diarrhea in the ICU setting. Many of the drugs commonly used in the ICU can cause diarrhea (Table 210.2). Therefore, any medication or combination of medications should be suspected, and uncertainty on the part of the physician warrants consultation with a pharmaceutical reference. Antibiotic-associated diarrhea occurs among 3% to 29% of hospitalized patients [5]. The frequency of diarrhea varies considerably depending on the antibiotic administered. The rate of diarrhea associated with parenterally administered antibiotics is comparable to orally administered antibiotics, especially antibiotics excreted into the enterohepatic circulation. Antibiotics most commonly associated with diarrhea include ampicillin, tetracycline, clindamycin, azithromycin, clarithromycin, fluoroquinolones, and many of the cephalosporins [6]. Antibiotic agents often cause a nonspecific, noninflammatory diarrhea associated with nausea, abdominal cramping, and bloating. In these instances, diagnostic studies are generally negative. Fluid and electrolyte losses are minimal, and symptoms often abate after withdrawal or change of the medication. Alterations in intestinal flora, breakdown of dietary carbohydrate products, and prokinetic effects (e.g., from erythromycin) are all postulated mechanisms of diarrhea [7].

</table>
Clostridium difficile infection (CDI) is the most common cause of infectious diarrhea in the ICU [8]. In fact, residence in the ICU has been identified as a risk factor for developing CDI [9], and some authors believe that *C. difficile* toxins are responsible for 50% of the cases of diarrhea in the ICU setting. CDI in the ICU is increasing not only in incidence but also in severity [10]. CDI must always be considered for ICU patients with diarrhea who are commonly exposed to various medications, particularly antibiotics that predispose to the development of CDI. Classically, clindamycin, penicillin, and broad-spectrum cephalosporins have been implicated. However, CDI may be caused by any antibiotic, including metronidazole and vancomycin, the agents typically used to treat CDI. Besides antibiotic exposure and environmental factors, the risk factors associated with CDI, include age greater than 60, severe underlying disease, gastric acid suppression, and immunologic susceptibility [7].

*C. difficile* produces multiple toxins, two of which have been well characterized. Toxin-induced changes in colonocyte function, cytokine release, and alterations in intestinal motility result in the signs and symptoms characteristic of CDI [11]. It is considered complicated and severe when patients are admitted to the ICU, hypotensive requiring pressors, febrile (greater than 38.5°C), have ileus or significant abdominal distention, mental status changes, leukocytosis (more than 35,000 white blood cells [WBC] per μL), leucopenia (less than 2,000...
WBC per μL), elevated serum lactate levels (more than 2.2 mmol per L), or end-organ failure (mechanical ventilation, renal failure, etc.). Prompt recognition and treatment of CDI are essential because severe cases of CDI can progress to fulminant colitis and toxic megacolon requiring urgent surgical intervention [12].

Agents that increase the osmotic load in the gut lumen are also frequent causes of diarrhea in the ICU patient. Magnesium-containing antacids (e.g., Maalox and Mylanta) are common examples of such agents. The gut lumen osmotic load can also be increased as a result of aggressive enteral repletion of nutrients, such as magnesium and phosphorus. Lactulose, a useful agent in the treatment of hepatic encephalopathy, provides an osmotic gradient, resulting in increased fluid secretion and stool output. Many medications contain inert additives, sorbitol or lactose, which may also cause an osmotic diarrhea. In one study including 29 tube-fed patients with diarrhea, 48% of the cases were attributed to sorbitol-containing elixirs [13].

Proton pump inhibitors (PPIs), another commonly used class of medication in the ICU setting, frequently cause diarrhea, particularly when administered in higher doses. In fact, in a large study of more than 40,000 patients treated with omeprazole, lansoprazole, or pantoprazole, the most common adverse event was diarrhea [14].

Immunosuppressants used in transplantation (e.g., tacrolimus, sirolimus, mycophenolate mofetil, cyclosporine, and azathioprine) are associated with diarrhea. However, these agents may not be causative. As an example, an alternative explanation was found in 50% of kidney transplant patients who developed diarrhea while receiving mycophenolate [15]. In patients with HIV who are treated with highly active antiretroviral therapy, drug-induced diarrhea occurs in up to 75% of patients, and the protease inhibitors as well as integrase inhibitors are the most common drug-related cause of diarrhea in this population [16]. Symptoms are decreased by dose reduction or eliminated by discontinuation of therapy.

Withdrawal from medications (e.g., long-term sedatives, analgesics) may also be associated with diarrhea [17].

Other medications associated with diarrhea include colchicine, quinidine, digitalis, metoclopramide, theophylline, levothyroxine, aspirin, nonsteroidal anti-inflammatory drugs, misoprostol, cimetidine, diuretics, cholinergic agents (e.g., bethanechol), and β-blockers.

Enteral Feedings

Enteral feedings are the most common cause of diarrhea in the ICU setting, occurring in up to 63% of the ICU patients [1,18]. Numerous studies have investigated the role of enteral feedings in causing diarrhea
in the critically ill patient. Certain aspects, such as concurrent administration of antibiotics, osmolality of solution, type of solution, and serum albumin, have been assessed to determine their contributing roles in the occurrence and severity of diarrhea for these patients [19]. In most instances, diarrhea in enterally fed patients is associated with concurrent antibiotic administration [18,20]. However, enteral feeds also cause changes in gut function that can result in diarrhea. The osmolarity of the enteral solution may play a role when elemental-type diets are used, and especially when feedings are rapidly administered directly into the small intestine. Bolus feeding may be more physiologic, especially with regard to glucose homeostasis; however, feedings administered in this manner distal to the pylorus introduce high-osmolar contents rapidly into the small bowel, resulting in a higher incidence of diarrhea [21]. The impact of enteral nutrition-related complications, including diarrhea, was illustrated in a prospective, multicenter cohort study of 400 patients [22]. In this study, 62.8% (251 of 400) patients suffered GI complication with 14.7% of the studied patients experiencing enteral nutrition-related diarrhea. These authors found that patients with GI complications had a reduction in their tube feed volumes, longer length of stay in the ICU, and higher mortality.

Enteral formulas high in lactose or fat content may also be a factor in susceptible patients. Starved or chronically parenterally fed patients who have developed small bowel villus atrophy and a decrease in mucosal disaccharidase enzyme activity may experience diarrhea when enteral feedings are initiated.

The relationship between hypoalbuminemia and diarrhea is controversial. Hwang et al. [2] compared ICU patients with and without diarrhea and found that the albumin level was statistically different between groups (1.90 vs. 3.40 g per dL in the groups with or without diarrhea, respectively). Hypoalbuminemia with resulting lowered oncotic pressure may cause diarrhea by inducing changes in the Starling forces sufficient to inhibit intestinal fluid absorption. Some authors claim that concurrent nutritional intake and correction of the albumin deficit with intravenous salt-poor albumin may result in normalization and maintenance of albumin levels with an improved tolerance to enteral feedings and resolution of diarrhea [23]. Conversely, patients with severe hypoalbuminemia secondary to cirrhosis or nephrotic syndrome do not uniformly have diarrhea. Until further studies show efficacy, routine use of intravenous albumin repletion cannot be recommended.

Studies investigating the role of the intestinal response to tube feedings
have revealed that intraduodenal infusion resulted in a normal postprandial pattern of small intestinal motility and an increase in the volume of fluid entering the colon, but did not result in diarrhea [24]. Intragastric infusion, on the contrary, resulted in small intestinal motility and colonic flow similar to fasting, and the majority of subjects developed diarrhea [25]. This has led to the conclusion that enteral feeding–related diarrhea may be secondary to a disorder of colonic function. Further supporting this hypothesis are studies that have shown that the ascending colon, normally the site of maximal absorption of water and electrolytes, actually secretes water, sodium, and chloride during intragastric and intraduodenal infusion [26]. Up to 3.2 L per day was secreted by the ascending colon in these studies. Although this is well within the estimated 5.7 L per day maximal absorptive capacity of the colon, diarrhea still occurred, suggesting that this reversal of normal colonic physiology seriously impairs the absorptive capacity of the colon [27].

Diarrhea Secondarily Related to Underlying Disease

Diarrhea may result from various processes or pathogens associated with disease states commonly seen in the critically ill patient. Diarrhea may occur more frequently in patients who are immunosuppressed, have alterations in cardiac output and blood flow, or have various primary GI diseases.

In immunosuppressed patients, multiple infectious agents may be responsible for the development of diarrhea. Cytomegalovirus (CMV), herpes simplex virus, *Giardia, Salmonella, Shigella, Cryptosporidium, Isospora, Campylobacter*, and *Mycobacteria* are among the most common identifiable pathogens. Postchemotherapy patients can also experience diarrhea as a result of direct injury to the bowel, ranging from bowel edema to frank infarction. The cause of these changes is unclear; however, infections, direct toxic effects of chemotherapeutic agents, neutropenia, and primary intestinal injury have been postulated as initiating factors [28]. Strongyloides stercoralis should be remembered as a cause of diarrhea in patients who lived or traveled to endemic areas. Untreated immunosuppressed patients may develop hyperinfection with pulmonary infiltrates and infection of the cerebrospinal fluid and blood with enteric gram-negative bacilli [29].

In patients with acquired immunodeficiency syndrome (AIDS), diarrhea is perhaps the most commonly experienced symptom. Aside from iatrogenic causes, these patients can develop diarrhea from a single or multiple pathogens. CMV, *Mycobacterium* spp, *Cryptosporidium*, and *Microsporidium* are the most common agents. *Cryptosporidium* typically results in a severe large-volume secretory diarrhea (often in excess of 1 L
per day) [30]. Other pathogens such as *Entamoeba histolytica*, *Isospora belli*, *Giardia lamblia*, *Microsporidium*, adenoviruses, and other species described above are capable of causing diarrhea in patients with AIDS [31]. Bacillary dysentery may become chronic and relapsing, posing challenges with treatment. The herpes simplex virus may cause perianal ulceration, urgency, and frequent mucopurulent discharge, which may be interpreted as diarrhea [32]. The CD4 count (cluster of differentiation four count) indicates the degree of immunocompromise in these patients, and a lower count broadens the differential diagnosis of the etiology of diarrhea. *Cryptosporidium parvum*, *Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*, *Mycobacterium avium* complex (MAC), and enteroaggregative *Escherichia coli* cause self-limited disease in normal and mildly immunosuppressed individuals, but may cause persistent, severe diarrhea in patients with CD4 counts less than 200 cells per μL [33–37]. CMV rarely causes diarrhea in patients with CD4 counts greater than 50 cells per mm [38]. Patients with AIDS may also develop high-grade intestinal lymphomas predominantly of B-cell origin, which may present as diarrhea. Kaposi sarcoma may cause GI bleeding but rarely causes diarrhea [39].

Intestinal ischemia, especially involving the colon, may result in abdominal pain and diarrhea in the ICU patient. Postsurgical patients, especially those who have undergone repair of an abdominal aortic aneurysm, may have as high as a 6% incidence of colonoscopically documented ischemia [40]. Patients who have undergone an abdominoperineal resection or therapeutic angiography are also at risk. Compromise of the inferior mesenteric artery with left-sided colonic involvement is the primary etiologic factor. Symptoms may occur within hours to a few days following the procedure and may even be delayed for weeks. Patients in shock with depressed cardiac output may be more likely to present with right-sided colonic involvement, which is associated with a worse prognosis [41]. Severity can range from mild, transient ischemic changes to mucosal ulceration or bowel necrosis.

Sympathomimetic drugs, vasopressin, ergot preparations, migraine therapies, alosetron, bevacizumab, and digoxin may further place susceptible patients at risk [42]. Likewise, small intestinal ischemia, especially venous ischemia, may present with bloody or nonbloody diarrhea. Bleeding of either the upper or lower GI tract is a frequent cause of bloody diarrhea in the ICU setting. Blood acts as both an irritant and osmotic agent, resulting in diarrhea. Common causes of upper GI bleeding include esophagitis, gastric and duodenal ulcer disease, and hemorrhagic gastropathy; whereas infectious colitis, diverticulosis, and ischemia may result in lower GI bleeding.

Fecal impaction in both medical and surgical patients may cause diarrhea and should be considered in the ICU patient with diarrhea.
Drugs such as analgesics, sedatives, aluminum-containing antacids, and sucralfate may decrease intestinal motility and fecal fluidity, resulting in formation of a partially obstructing fecal mass and diarrhea. Diverticulitis may also be present with an accompanying diarrhea.

## Diarrhea as a Primary Manifestation of Disease

Several common diseases are occasionally characterized by diarrhea during their courses. For instance, patients with diabetes can experience severe bouts of diarrhea. Diabetic diarrhea is considered to result from an autonomic neuropathy and its subsequent effect on intestinal fluid absorption [43]. These patients invariably have other signs of autonomic neuropathy, including orthostatic hypotension, gastroparesis, anhidrosis, abnormalities in RR wave variation on electrocardiogram, and neurogenic bladder [44]. Abnormalities in motility with intestinal stasis and bacterial overgrowth may also play a role in the development of diarrhea in diabetic patients.

Other endocrine disorders such as adrenal insufficiency and hyperthyroidism should also be considered in the critically ill patient with diarrhea. Adrenal insufficiency, either primary adrenal failure as a result of bilateral adrenal hemorrhage or infarction, or relative deficiency induced by stress in patients chronically exposed to corticosteroids, may present with secretory diarrhea. The symptoms and signs of an adrenal crisis include shock, nausea, vomiting, diarrhea, abdominal pain, fever, fatigue, and sometimes confusion or coma. Patients with hyperthyroidism have increased fecal output largely owing to increased intestinal motility [45].

Graft-versus-host disease (GVHD) may complicate both the short- and long-term course of patients who have undergone transplant (most commonly following allogeneic hematopoietic stem cell transplantation) [46,47]. Acute GVHD, occurring less than 100 days after transplant, typically is characterized by dermatitis, hepatitis, and gastroenteritis usually manifesting with nausea, abdominal pain, and diarrhea. Chronic GVHD (occurring more than 100 days after transplantation) may mimic autoimmune diseases, such as systemic lupus erythematosus, systemic sclerosis, or Sjogren syndrome [48] and often is characterized by a less severe form of diarrhea.

Vasculitic diseases such as systemic lupus erythematosus, dermatomyositis, polyarteritis, and granulomatosis with polyangiitis can involve medium- and small-sized vessels supplying the G1 tract.
Abdominal pain, fever, bleeding, and diarrhea are common resulting symptoms.

Finally, one must always consider the causes of diarrheal disease that are not unique to the critically ill patient. Infectious causes of diarrhea for immunocompetent hospitalized patients are possible, but are unusual in clinical practice unless the onset of the diarrhea is within the first few days of hospitalization or a nosocomial outbreak of infection is present [49]. Infectious causes that should be considered include *Salmonella, Shigella, Campylobacter, Giardia*, or *E. histolytica*, although other pathogens have also been implicated [50]. Nonenteric infectious causes of diarrhea include toxic shock syndrome and Legionnaires disease. Other causes to be considered include lactose intolerance, inflammatory bowel disease, and celiac sprue.
DIAGNOSIS

History and Physical Examination

The history is important in establishing the diagnosis and etiology of diarrhea in the ICU patient; however, depressed neurological function as the result of the disease state or iatrogenic sedation and intubation may make obtaining a history impossible. Attention to onset, duration, character, relation to enteral intake, and associated symptoms of diarrhea may be helpful etiologic clues. Information on prior episodes of diarrhea, the patient’s underlying medical conditions (which may be associated with diarrhea), or prior use of antibiotics is also important to elucidate. Next, a careful review of the patient’s current medications and their administration relative to the onset of diarrhea should be performed. Any suspected agent should be discontinued if at all possible or changed to an alternative medication. Every effort should be made at decreasing the number of medications and continuing only those that are absolutely necessary. The physician should also determine whether the initiation of enteral feedings has correlated with the onset of symptoms.

A history of abdominal pain may suggest ischemia, infection, or various inflammatory conditions such as vasculitis or GVHD. Bloody diarrhea may suggest primary GI bleeding, ischemia, or occasionally pseudomembranous colitis secondary to CDI. Passage of frequent small-volume stools with urgency and tenesmus suggests distal, left-sided colonic involvement, whereas passage of less frequent, large-volume stools suggests more proximal involvement (small intestine or right colon). These historic clues, however, are not mutually exclusive, and, in disease states with extensive bowel involvement, the distinction may not be appreciable.

Physical examination may provide further clues to the etiology of diarrhea, but findings are usually nonspecific. More important, the physical examination is essential in assessing the clinical severity of diarrhea. Orthostasis suggests severe volume loss, adrenal insufficiency, or autonomic neuropathy (e.g., from diabetes). Fever may occur in individuals with infection, vasculitis, adrenal insufficiency, or hyperthyroidism. Abdominal tenderness may suggest infectious, ischemic, or vasculitic causes. Skin rashes or mucosal ulcerations in appropriate patients may suggest inflammatory bowel disease, vasculitis, or GVHD. Clinical manifestations of AIDS may be apparent. Abdominal distention, palpable bowel loops, or abnormal rectal examination may suggest a partially obstructing fecal impaction.
Laboratory Studies

Serum electrolytes especially sodium, potassium, magnesium, and phosphorus should be obtained and carefully monitored in patients with diarrhea. Severe diarrhea may result in a hyperchloremic metabolic acidosis and prerenal azotemia. The serum sodium may be normal, elevated, or depressed depending on the severity of diarrhea, oral/parenteral water intake, type of intravenous fluid administered, and other disease states (e.g., hepatic or renal dysfunction). The serum potassium, magnesium, and phosphorus may be normal or depressed, whereas elevations (e.g., in potassium) may suggest adrenal insufficiency or uremia. Leukocytosis may suggest infection or ischemia, whereas neutropenia may suggest an immunosuppressed state or sepsis. Low serum protein levels may be a clue to the presence of a protein-losing gastroenteropathy.

Examination of the stool may be the single most important and most overlooked laboratory investigation in the ICU patient with diarrhea. The presence of fecal leukocytes should be determined, and when present may suggest infection, ischemia, or mucosal inflammation. Newer assays for fecal calprotectin and lactoferrin have been validated for use in dysentery and inflammatory bowel disease, but its usefulness in the ICU setting requires study [51]. Because of the high false-positive rate, *C. difficile* should only be tested in patients with current symptoms of diarrhea. The nucleic acid amplification tests for *C. difficile* toxin gene such as polymerase chain reaction is a standard diagnostic test for CDI and is superior to toxins A + B enzyme immunoassay testing. Once the diagnosis is made, repeat testing is discouraged. Several studies have shown that repeat testing after a negative test is positive in <5% of specimens, thereby increasing the likelihood of false positives [52–54]. On the other hand, when the test comes back negative, empiric treatment for CDI should not be discontinued or withheld in patients with a high pretest suspicion for CDI. That meant, the treatment is monitored by clinical symptoms and not with repeat testing because the stool can remain positive for at least 30 days after the diagnosis is made.

Fresh stool specimens for culture and ova and parasite examination should be requested in patients where there is a clinical suspicion, for example, in dysenteric presentations or when either fecal leukocytes or an elevated fecal calprotectin is found. Indiscriminate ordering of stool culture and ova and parasite test is not warranted. Immunosuppressed patients, however, require more extensive examination of the stool. Often, opportunistic pathogens are not detected readily through stool studies, and endoscopic examination with biopsies is required. Some pathogens such as CMV or MAC isolated from stool do not necessarily represent infection and require evidence of tissue invasion on biopsy for
diagnosis.
Qualitative examination of the stool for fat using a Sudan III stain is the best screening test if a malabsorptive state is suspected. Determination of the stool osmolar gap, which is \(290 - ([\text{stool Na}^+] + \text{stool K}^+] \times 2)\), helps to distinguish osmotic and secretory causes of watery diarrhea. A gap greater than 125 mOsm per L is conventional for an osmotic diarrhea. High-volume stool output that persists with fasting suggests a secretory etiology. A low stool pH may suggest bacterial overgrowth or carbohydrate malabsorption [4].

---

**Special Diagnostic Investigations**

Plain abdominal radiographs are sometimes helpful and may show signs of ischemia, obstruction, perforation, or a megacolon associated with colitis. Contrast studies better define GI pathology that may result in diarrhea but often cannot be performed in a critically ill patient. Both these studies have been, in practice, supplanted by computed tomography (CT); newer imaging modalities, such as CT enterography and magnetic resonance enterography, have replaced the more cumbersome enteroclysis and may be useful in selected cases.

Flexible sigmoidoscopy, colonoscopy, and upper endoscopy can be extremely useful in diagnosing various causes of diarrhea. Colitides, including infectious, ischemic/vasculitic, and pseudomembranous colitis, will often have a characteristic endoscopic appearance. The classic findings in *C. difficile* colitis include distinct, adherent, raised plaques (pseudomembranes) 2 to 5 mm in size that may be confluent. More commonly, the mucosa is normal: a normal appearance should not exclude the diagnosis of CDI, because mucosal biopsies may reveal pseudomembranes histologically. CMV or herpes colitis are best diagnosed endoscopically. CMV colitis may manifest as discrete ulcerations or widespread mucosal edema, erythema, and erosion. The characteristic vesicles of herpes may or may not be present and can be replaced by extensive ulceration. MAC (aforementioned) is usually diagnosed histologically; small bowel or colonic biopsies reveal abundant acid-fast bacilli. *Cryptosporidium* and *Giardia* can be made by histologic evaluation of small bowel biopsies, whereas identification of *Microsporidium* is more difficult and requires the use of electron microscopy. GVHD is confirmed most commonly by histopathologic findings seen in biopsies obtained during flexible sigmoidoscopy.

Video capsule endoscopy, where a 12-mm capsule is either swallowed or placed in the small bowel endoscopically, captures via telemetry
images of the entire small bowel. The mucosal detail provided is excellent, and so small bowel ulcerations, villus abnormalities, strictures, and other mucosal lesions are now more readily detected. In addition, small bowel ulcerations, villus abnormalities, strictures, and other mucosal lesions are now more readily detected. For example, capsule endoscopy allows for a more precise gauge of the extent of Crohn disease and celiac disease, and eosinophilic gastroenteritis has a characteristic capsule endoscopic appearance [55]. Although this technology permits detection of occult small bowel pathology not previously appreciated, its possible role and value in the diagnosis of persisting diarrhea in the ICU patient is unknown.
MANAGEMENT

Initial Management

The first and most important step in management of patients with diarrhea regardless of the etiology is correction of fluid and electrolyte imbalances (Fig. 210.1). Careful monitoring of the patient’s physical and laboratory parameters will help guide replacement therapy. Most often, free water, sodium, potassium, phosphorus, or magnesium repletion will be required. If fluid losses are particularly severe or the patient’s circulatory status is tenuous or compromised, central venous access and monitoring are essential. Physicians and nursing staff should ensure that proper patient hygiene and skin care are maintained. Suspected infectious causes of diarrhea warrant patient isolation and enteric precautions until a diagnosis is made and proper treatment instituted. Infection control is essential to prevent spread of the disease in the unit. Hospital-based infection control programs are needed to help decrease the incidence of CDI. Intensivists should work on reducing the risk of CDI by antibiotic stewardship as much as possible.

FIGURE 210.1 Algorithm for management of diarrhea in the intensive care unit.

Therapy of Iatrogenic Causes

Iatrogenic causes of diarrhea are among the most readily diagnosed and easily treated etiologies. Suspect medications, especially antibiotics,
should be withdrawn or changed to those that are less likely to cause diarrhea.

If a diagnosis of *C. difficile* colitis is suspected or made, the offending antibiotic should be discontinued, or if necessary, replaced by agents that are less likely to cause CDI (Table 210.3). By definition, *C. difficile* colitis that is diagnosed in the ICU is considered complicated and should be treated as such. Management of mild-to-moderate disease will not be treated in the current chapter. That meant, if a patient, who is in the ICU, has a strong pretest suspicion for CDI, empiric therapy should be considered regardless of the laboratory testing result, because the negative predictive values are insufficiently high to exclude disease in these patients. The treatment regimen depends on the patients’ condition. If they do not have significant abdominal distention, they should be treated with vancomycin 125 mg orally four times a day plus metronidazole 500 mg intravenously three times a day. If they have ileus or toxic colon and/or significant abdominal distention, they should be treated with vancomycin 500 mg orally and per rectum four times a day plus metronidazole 500 mg intravenously three times a day. Treatment with PO vancomycin has been a time-honored and highly efficacious therapy, resulting in improvement in more than 95% of patients [56]. Oral route for vancomycin is the preferred route, but in patients in whom oral antibiotics cannot reach a segment of the colon, such as with Hartman pouch, ileostomy, or colon diversion, vancomycin therapy delivered via enema should be added to the oral treatment until the patient improves. Intravenous vancomycin should not be used to treat CDI, because it is not excreted in the stool [57,58]. All patients with complicated CDI should get a CT scan of the abdomen/pelvis and a surgical consult. Surgical therapy should be considered in patients who have a complicated and severe CDI or failed to improve on medical therapy after 5 days. Antiperistaltic agents should be limited or avoided in patients with confirmed or even suspected CDI. Oral or enteral feeding should be continued in the absence of ileus or abdominal distention. Relapse rates may be high, occurring in as many as 24% of patients [59]. There is moderate evidence that two probiotics (*Lactobacillus rhamnosus* GG and *Saccharomyces boulardii*) can decrease the incidence of antibiotic-associated diarrhea, but there is insufficient evidence that they prevent CDI [12].

Isolation with enteric precautions

Antimicrobial

- Metronidazole 500 mg PO/IV t.i.d. for 10–14 d
- Vancomycin 125–500 mg PO q.i.d. for 7–14 d

PO, orally; IV, intravenous; t.i.d., three times a day.

Data are now emerging that exposure to PPIs is associated with increased odds of CDI in hospitalized patients. The postulate that acid suppression causes enteric infections seems reasonable but remains controversial. These data are observational and, thus, may be subject to uncontrolled confounding. Nonetheless, it is prudent to review the indication for PPI prescription in all patients and restrict use of these drugs appropriately [60].

Antimotility agents should not be used in colitis, because they may lengthen the course of illness and may precipitate toxic megacolon [61]. If the patient with *C. difficile* colitis develops peritoneal signs, bacteremia unresponsive to antibiotics, progressive fever, rigors, or radiologic evidence of significant pericolonic inflammation with increasing bowel wall edema, then surgical intervention is indicated [62]. The recommended procedure is subtotal colectomy with ileostomy, with possible ileorectal anastomosis after the inflammation has subsided.

There are several controlled trials now available which demonstrate the effectiveness of octreotide in chemotherapy and radiation-associated acute diarrhea. In these studies, doses range of 100 to 500 μg is given subcutaneously twice or three times daily. Budesonide is not helpful in these settings [63].

Enteral feedings suspected of causing diarrhea should be reduced in volume, given by continuous infusion or temporarily discontinued. Lactose-free feeds should be used, because the high incidence of stress-induced GI mucosal injury in the ICU population affects loss of disaccharidase activity. Fiber-containing formulas or fiber added to standard formulas may benefit ICU patients with tube feeding-associated diarrhea [64,65]. Elemental diet supplements may also be considered in patients with short bowel syndrome, pancreatic insufficiency, radiation enteritis, fistula, and inflammatory bowel disease. Their major disadvantages are high cost and increased osmolarity [66].

**Treatment of Diarrhea Related to Disease**

Efforts should always be made to treat the underlying disease-causing diarrhea for the critically ill patient, although such efforts may or may not improve the diarrhea. Diarrhea secondary to sepsis will typically resolve, because the source of sepsis is treated, whereas diarrhea secondary to
Diabetes or uremia may not improve despite treatment of the primary disease.

Diarrhea-causing pathogens should, in general, be treated. The detection of *Blastocystis hominis* by parasite exams may indicate co-infection with other pathogens, and empiric nitazoxanide or metronidazole may be beneficial [67]. Infections in patients with AIDS and other immunocompromised settings are treatable with currently available therapy [68,69].

Patients with ischemic colitis without transmural necrosis may be managed with supportive care. Drugs that exacerbate ischemia should be discontinued if possible. Aggressive efforts at maintaining circulatory blood volume and maximizing oxygen delivery should be emphasized. Signs of infarction or perforation warrant operative management.

Fistulas should be managed by bowel rest or surgery depending on the clinical circumstances. Postcholecystectomy diarrhea may respond to bile acid sequestrants, such as cholestyramine. Surgically induced cases of short bowel syndrome or malabsorption may be aided by enteral nutrition in the form of elemental diets or, if unsuccessful, parenteral nutrition. Fecal impactions should be removed by manual disimpaction followed by cleansing enemas consisting of tap water, sodium phosphate, or diatrizoate (water-soluble contrast) enemas. More proximal and firm impactions can be broken up using a sigmoidoscope and an irrigating device by directing a water jet into the fecal mass under direct vision. Prevention following treatment with appropriate laxatives or enemas is paramount.

### Treatment of Diarrhea as a Primary Manifestation of Disease

Every effort should be made to treat the disease responsible for the diarrheal syndrome. General supportive measures previously discussed should also be employed in all patients. Diseases such as vasculitis should be managed with corticosteroid or immunosuppressive therapy. Adrenal insufficiency will respond promptly to the administration of corticosteroids. Hyperthyroid patients should receive appropriate therapies. GVHD should be managed with corticosteroids and immunosuppressive agents. The chronic form of the disease may be more effectively treated, whereas the acute variety may be less responsive, with a substantial mortality rate. Treatment of the inflammatory bowel diseases is addressed in Chapter 211, but generally includes aminosalicylates, corticosteroids, immunomodulating agents, biologics, and surgery. Celiac sprue will respond to supportive measures and a gluten-free diet.
Palliative Measures

The aforementioned diagnostic and therapeutic approaches will result in proper diagnosis and directed treatment in a majority of patients with diarrhea in the critical care setting. In a modest number of patients, however, a cause for diarrhea will not be found or a specific treatment will not be readily available. For this category of patients, palliative therapies are available with the goal to decrease fluid losses, patient discomfort, and morbidity (Table 210.4). Antimotility agents such as loperamide, diphenoxylate with atropine, and deodorized tincture of opium (DTO) may decrease frequency and severity of diarrhea in patients with diarrhea of unclear etiology or diarrhea because of enteral feeding or other noninfectious causes. Advantages of loperamide include the absence of central nervous system activity and resultant side effects, whereas DTO is administered in drop form, enhancing dosing flexibility. Octreotide can be used for palliation of diarrhea in patients with AIDS, GVHD, hormone-producing tumors, radiation- and chemotherapy-induced diarrhea, and other causes of secretory diarrhea [70].

tsp, teaspoon.
CONCLUSION

Diarrhea is a frequently occurring complication in the ICU setting. It is a symptom that tends to be overshadowed by other processes in the ICU, but in and of itself may result in significant morbidity. In most instances, it can be managed following institution of proper diagnostic, therapeutic, or palliative measures.
REFERENCES

Ulcerative colitis is characterized by a diffuse, continuous inflammatory process usually limited to the superficial mucosa of the colon. Fulminant colitis implies progression of mucosal inflammation into deeper (muscular) layers of the colon wall. It generally is associated with severe bloody diarrhea, fever, tachycardia, and abdominal tenderness. Systemic manifestations result from transmural colitis, which may also produce circular muscle paralysis precipitating dilatation. Toxic megacolon refers to acute dilatation of the colon, generally as a complication of ulcerative colitis, but it may occur with any severe inflammatory colitis. Toxic megacolon has been described with inflammatory bowel disease (Crohn disease and ulcerative colitis), and infectious colitis, including amebic colitis, pseudomembranous colitis, and other infections [1]. Two to 8% of patients with *Clostridium difficile* infection will progress to fulminant colitis carrying a mortality rate ranging between 13% and 80% [2]. Toxic megacolon has been reported to complicate from 1% to 10% of all ulcerative colitis cases and from 2% to 3% of Crohn colitis cases [1]. Although mortality from early series was as high as 25% (reaching 50% if colonic perforation occurred), early recognition and management of toxic megacolon have substantially lowered mortality to below 15% [3] and usually below 2% at experienced centers [4]. Factors associated with increased mortality include age older than 40 years, the presence of colonic perforation, and delay of surgery [3,4]. Colonic perforation, whether free or localized, is the greatest risk factor leading to increased morbidity or death.

PREDISPOSING FACTORS
The severity of disease activity is the most important predictor of toxic megacolon, which is more common for extensive colitis than for proctitis or proctosigmoiditis [5]. Limited right- or left-sided segmental colitis also has been associated with toxic megacolon. Concomitant C. difficile infection often occurs in hospitalized patients with inflammatory bowel disease and can be associated with refractory disease [6,7]. Similarly, cytomegalovirus (CMV) infections frequently complicate severe colitis with a reported prevalence rate of 4.5% to 16.6% in the setting of immune suppression with corticosteroids or cyclosporine, with a prevalence rate as high as 25% in patients requiring colectomy [8,9]. Treatment of CMV with ganciclovir is controversial; however recent data have shown improved surgery-free outcomes after CMV therapy particularly in patients with a high-grade CMV density on colonic biopsies, defined as 5 or more CMV nuclear inclusions [10].

Toxic megacolon typically occurs early in the course of ulcerative colitis, usually within the first 5 years of disease, and 30% of cases present within 3 months of diagnosis of the initial attack [11]. The onset of toxic megacolon has also been linked to patients who have recently undergone diagnostic examinations, such as barium enemas or colonoscopy, suggesting that manipulation of the inflamed bowel or vigorous laxative preparation may exacerbate the process, possibly through electrolyte imbalance (Table 211.1) [3,12].

CMV, cytomegalovirus.

Certain drug therapies have been implicated for the development of toxic megacolon. Diphenoxylate hydrochloride/atropine sulfate (Lomotil), loperamide, and other inhibitors of colonic motility such as narcotics may contribute to the development of toxic megacolon by

Despite early speculations on the role of corticosteroids in inducing toxic megacolon, most experienced clinicians do not accept the implication that corticosteroids or adrenocorticotropic hormone are precipitating factors [1,13]. Concern remains, however, that corticosteroids may suppress signs of perforation, thereby delaying surgical therapy [11].

*C. difficile* infection can progress to fulminant colitis in and of itself, and a WBC > 20,000 μL or <2,000 μL, elderly >70 years, cardiorespiratory failure, or diffuse abdominal tenderness are predictors of worse outcomes and progression to fulminant colitis [2].
Toxic megacolon usually occurs on the background of chronic inflammatory bowel disease \([1,11,13]\). The presentation typically evolves with progressive diarrhea, bloody stool, and cramping abdominal pain. Occasionally, patients treated for inflammatory bowel disease over long periods of time have a paradoxical decrease in stool frequency with passage of only bloody discharge or bloody membranes; this can be an ominous sign (Table 211.2). Thereafter, clinical signs of toxemia, including pyrexia (temperature > 101.5°F), tachycardia (heart rate > 120 beats per minute), leukocytosis (total white blood cell count > 10,500 cells per μL), and anemia develop. The abdominal pain and distention become progressive and bowel sounds diminish or cease. Signs of peritoneal irritation, including rebound tenderness and abdominal guarding represent transmural inflammation to the serosa, even in the absence of free perforation. Conversely, peritoneal signs may be minimal or absent in elderly patients or those receiving high-dose prolonged corticosteroid therapy or narcotics for pain control. In such patients, loss of hepatic dullness may be the first clinical indication of colonic perforation. Mental status changes, including confusion, agitation, and apathy, occasionally are noted. Leukocytosis with a left shift generally is present. Anemia, hypokalemia, and hypoalbuminemia are common. The presence of anemia, requirement for transfusion, hypoalbuminemia, malnutrition, and prolonged hospitalization are poor prognostic factors \([14–17]\).

Abdominal CT:
- Segmental thinning of the colonic wall
- Nodular pseudopolyposis

Endoscopic findings:
- Extensive ulceration with friable and bleeding mucosa
- Deep ulcerations

Laboratory test findings
- White blood cell count > 10,000/μL, with pronounced left shift
- Anemia (may not be reflected in initial measurement if dehydrated)
- Hypernatremia (if dehydrated)
- Hypokalemia
- Metabolic alkalosis (diarrhea)/acidosis (sepsis)
- Hypomagnesemia
- Hypophosphatemia
- Hypoalbuminemia

Plain films of the abdomen usually are sufficient radiographic studies, revealing loss of haustration with segmental or total colonic dilatation. Clinical studies have demonstrated a strong correlation between colonic dilatation and deep ulceration involving the muscle layers [18]. The magnitude of dilatation may not be severe, averaging 8 to 9 cm (normal is <5 to 6 cm), although colonic diameter may reach 15 cm before rupture. Maximal dilatation can occur in any part of the colon. Accompanying mucosal thumbprinting or pneumatosis cystoides coli reflect severe transmural disease. Free peritoneal air should serve as an immediate indication for surgery [3]. Infrequently, retroperitoneal tracking of air from a colonic perforation may produce subcutaneous emphysema and pneumomediastinum without pneumoperitoneum. In patients with severe colitis, small bowel ileus may herald toxic megacolon and is a bad prognostic sign for successful medical management. Discrepancies may exist between physical and radiographic findings. Abdominal distention by physical examination can be minimal despite massive colonic dilatation. Conversely, physical findings may dominate the presentation, and peritoneal signs in the absence of free air or dilatation should not be ignored. Computed tomography scans can demonstrate segmental thinning of the colonic wall, nodular pseudopolyposis and air-filled colonic distention over 6 cm or evidence of perforation or abscess [1,19].
Early flexible sigmoidoscopy within the first 48 hours should be performed by an experienced endoscopist to assess severity of disease and obtain biopsies for CMV infection [11,13]. Endoscopic examination generally shows extensive ulceration with friable, bleeding mucosa. In rare instances, however, such as with rectal enema therapy or Crohn disease, the rectum may be normal [20]. More extensive endoscopic examinations, although controversial, generally are contraindicated. If performed, the presence of severe colitis (deep penetrating ulcers) in conjunction with clinical features of severe disease is a poor prognostic sign [18]. Similarly, the presence of extensive and deep ulcerations is a poor prognostic marker of Crohn disease [20].
MANAGEMENT

Few medical emergencies require as close cooperation between medical and surgical personnel as fulminant colitis and toxic megacolon \([1,13]\). A team approach with early management and continuous assessment is vital not only to determine whether surgery is indicated, but also to support the critically ill patient preoperatively and postoperatively. Early recognition and institution of therapy by an experienced team can alter the outcome of this life-threatening illness (Table 211.3).

**TABLE 211.3 Management of Toxic Megacolon**

Team approach toward management, including medical and surgical personnel  
Resuscitation and stabilization—electrolyte and fluid repletion, central venous pressure measurements, blood transfusions to maintain hematocrit greater than 30%, broad-spectrum antibiotics, administration of intravenous corticosteroids (e.g., methylprednisolone, 40–60 mg/d, and hydrocortisone, 400 mg/d)  
Evaluate status—abdominal examination every 6 h, radiographs of abdomen every 12–24 h  
Surgical intervention required for clinical deterioration at any time, failure of medical management to improve status within 48 h, evidence of perforation, shock, persistent hemorrhage  
Consider cyclosporine or infliximab for nontoxic patients without response to intravenous corticosteroids by day 3

Medical Treatment

Despite the fact that “bowel rest” is ineffective as primary therapy for severe colitis, oral intake of fluids should be discontinued in fulminant colitis or once colonic dilatation is recognized due to a possible imminent surgical procedure \([1,11,13]\). Total parenteral nutrition should be considered for patients at risk for malnutrition. A nasogastric tube is indicated for patients with associated small bowel ileus; however, it is not helpful for colonic decompression \([11,13]\). Rolling the less toxic patient from front to back may redistribute colonic air and assist in decompression. Rarely, patients who have been made “nothing by mouth” with colonic dilatation in the absence of toxic signs or symptoms may benefit from resumption of oral feeding. Anticholinergic and
narcotic agents should be discontinued [11,13]. Venous thromboembolism prophylaxis, preferably heparin or low-molecular weight heparin, should also be initiated in all patients hospitalized with severe or fulminant colitis. In ulcerative colitis, studies have shown a sixfold increased risk for thromboembolic events in hospitalized patients when compared to patients treated in the outpatient setting [21–23].

Resuscitative measures, including vigorous fluid, electrolyte, and blood replacement, are paramount. Extracellular fluid loss may be severe and, when combined with a low oncotic pressure from hypoalbuminemia, the hemodynamic state often is unstable. The goal of fluid replacement should be to restore previous losses and continue replenishing ongoing losses from diarrhea, fever, and third spacing of fluids. Transfusion of packed red blood cells should be instituted to maintain the serum hematocrit above 30%. Although severe hypokalemia may not be present, total body potassium depletion is common, and resuscitative measures should include adequate potassium replacement. Phosphate, calcium, and magnesium depletion should be corrected parenterally.

Aminosalicylates, a mainstay of maintenance therapy and the treatment of mild-to-moderate disease, have no role in the treatment of fulminant colitis or toxic megacolon. Their activity, limited to superficial inflammation, is insufficient to abort or control the transmural disease, while the potential adverse effects (e.g., nausea, vomiting, or worsening colitis) may confuse the clinical picture [24]. They should be withheld until the patient has recovered and resumed a normal diet.

Despite the absence of data, most experienced centers continue to administer broad-spectrum antibiotics in the setting of toxic megacolon. Antibiotics with adequate Gram-negative and anaerobic coverage are usually administered without delay once transmural inflammation or toxic megacolon is suspected [11,24]. Antibiotics are continued until the patient stabilizes over several days to a week, or through the initial postoperative period. Nonetheless, the ultimate benefits (or risks) have not been adequately determined.

Corticosteroids have long been used for the management of ulcerative colitis as well as in Crohn colitis. In general, parenteral corticosteroids are essential for patients with toxic megacolon, and most patients are likely to be receiving the drugs before toxic megacolon develops [13]. Augmented doses of corticosteroids should be administered in view of the additional stress of the toxic state. There is no general agreement regarding which corticosteroid preparation or dose should be given. Hydrocortisone, 100 mg every 6 hours, and methylprednisolone, 20 to 30 mg every 12 hours, also are available for intravenous (IV) administration. A continuous infusion of corticosteroids may be beneficial to maintain steady plasma levels; however, a study comparing bolus regimen to continuous steroid infusion found similar rates of clinical remission and
colectomy at 1 year [13]. Patients who fail to respond with a reduction in bowel movements, cessation of transfusion requirements, and improvement of C-reactive protein by day 3 are unlikely to respond and rescue therapies should be considered [13,25,26]. Additional tests in anticipation of rescue therapies should be performed early during hospitalization. Tuberculosis exposure should be assessed with a tuberculin skin test or interferon-γ release assay and a chest X-ray. Testing for hepatitis B should be done with hepatitis B surface antigen, hepatitis B core antibody, and surface antibody to screen for immunity in case anti-TNF biologic agents are considered.

Cyclosporine, a calcineurin inhibitor, was the first rescue therapy used to treated severe refractory ulcerative colitis [13]. A small randomized pilot trial showed that cyclosporine given at a dose of 4 mg/kg/d is also an effective single therapy (without steroids) to induce clinical remission for severe ulcerative colitis patients [27]. A trial comparing 2 mg/kg/d with 4 mg/kg/d of cyclosporine in conjunction with corticosteroids for severe colitis demonstrated that the lower dose was equally efficacious with less adverse effects [28]. Our center routinely adjusts the cyclosporine dose based upon serum levels checked 48 hours after initiation of therapy. Total daily dose should be adjusted to achieve a therapeutic level within the range of 250 to 400 mcg per L. Patients who are started on cyclosporine should be closely monitored for hypertension, tremors, seizures, opportunistic infections, nephrotoxicity, hypocalcemia, and hypomagnesemia. Individuals with hypocholesterolemia (total <120 mg per dL) or hypomagnesemia (<1.5 mg per dL) have a higher risk of seizures, and the initial cyclosporine dose should be reduced [13]. The role of cyclosporine for toxic megacolon remains controversial [29]. Patients who respond to IV cyclosporine should be transitioned to oral cyclosporine at 5 mg/kg/d and azathioprine should be started concomitantly. Patients will undergo a cyclosporine taper over 3 to 6 months, and should be maintained on trimethoprim–sulfamethoxazole for opportunistic infections prophylaxis during this time periods. There are scant data regarding the long-term outlook after cyclosporine therapy for fulminant or severe colitis, however patients who respond and are maintained on azathioprine have improved long-term outcomes [30].

The biologic chimeric antitumor necrosis factor monoclonal antibody, infliximab, has been used to treat moderate to severely active UC [13]. Formal studies have not been performed in the setting of fulminant colitis or toxic megacolon, although, in the setting of severe colitis in hospitalized patients, infliximab may have acute benefits [13]. Recent
data has suggested that an accelerated infliximab loading dose regimen with 3 doses given within 24 days significantly decreases the colectomy rate at 3 months when compared to standard loading dose schedule in severe UC patients [31]. This improved response is likely attributed to increased serum levels counter balancing the higher infliximab fecal loss in patients with severe disease [32].

Two recent studies have compared infliximab to cyclosporine in inducing clinical remission in patients with severe ulcerative colitis refractory to IV steroids. Cyclosporine was not more effective than infliximab in inducing clinical remission in this patient population [33,34]. Therefore, both are reasonable first-line options, and the rescue therapy choice should be based on patient’s prior medication response, physician’s experience and patient’s compliance. Current data are reassuring regarding the lack of increased postoperative complications and delay in colectomy for patients on rescue therapies [35]. There is paucity of data regarding the number of rescue therapies one should use in refractory patients, however most tertiary centers agree that surgery should be the treatment of choice should patients fail one rescue therapy by day 7. A summary of the evidence-based medical management approaches for fulminant colitis and toxic megacolon is provided in Table 211.4 and a recently proposed algorithm by Narula et al. is presented in Fig. 211.1.

Identify and admit patient with severe UC

Any indication for surgery? (i.e. perforation, toxic megacolon, life-threatening hemorrhage)

Yes:
Refer for colectomy.

No:
Rule out infections, offer VTE prophylaxis & oral feeds. Treat with IV corticosteroids X 72 hours.

Non-response:
Consider medical rescue therapy or surgery.

Response:
Switch to oral steroids and taper. Discuss maintenance strategy.

Surgery:
Refer for colectomy.

Medical Rescue Therapy:
IFX or IV CsA. Assess response after 7 days.

Response:
If IFX, complete IFX induction followed by IFX maintenance. If CsA, switch to oral CsA and bridge to azathioprine/6MP.

Non-response

Surgery:
Refer for colectomy.

Sequential rescue therapy:
Proceed with caution in specialized centres only.

FIGURE 211.1 Proposed algorithm for the treatment of hospitalized patients with severe ulcerative colitis.
Resuscitative measures for fulminant infectious colitis resulting in toxic megacolon should be initiated in the same manner as for idiopathic ulcerative colitis. Broad-spectrum antibiotic coverage should be followed by pathogen-specific therapy after the causative organism has been identified. In the setting of severe or fulminant *C. difficile* colitis, oral vancomycin 125 mg four times a day in combination with IV metronidazole 500 mg three times a day is considered the treatment of choice. For patients with an associated ileus or toxic megacolon, the American College of Gastroenterology recommend a higher oral vancomycin dose of 500 mg four times a day in combination with per rectum vancomycin 500 mg in a volume of 500 mL four times a day plus IV metronidazole as described above [7,23]. More recently, fecal microbiota transplant has been considered for patients with severe *C. difficile* infection, and some centers have used it with caution in fulminant colitis nonresponsive to standard therapy for 48 hours [36].

**Surgical Intervention**

When no improvement or if deterioration occurs, despite 12 to 24 hours of intensive medical management, surgical intervention is required for toxic megacolon [1]. Failure to substantially improve within 3 days of intensive corticosteroid therapy and within 7 days of rescue therapies is indications for surgery [1,13,25,26]. Some physicians actually view early surgical management of toxic megacolon as the conservative approach, noting that delay of operative therapy may promote higher mortality [15,37].

Evidence of colonic perforation is an unequivocal indication for emergent surgery. If physical signs of perforation are absent, 12- to 24-hour radiographic surveillance is necessary. Perforation is associated with severe complications, including peritonitis, extreme fluid and electrolyte imbalance, and hemodynamic instability. Early recognition of perforation should lessen morbidity or mortality [1]. Other indications for emergent surgery precluding protracted medical management include signs of septic shock and imminent transverse colon rupture (diameter > 12 cm). Hypoalbuminemia, persistently elevated C-reactive protein or erythrocyte sedimentation rate, small bowel ileus, and deep colonic ulcers are poor prognostic factors for successful medical therapy [17].

For infectious etiologies such as *C. difficile* colitis, surgery is indicated...
if there is any sign of hypotension requiring vasopressor therapy, clinical signs of sepsis and organ dysfunction (renal and pulmonary), mental status changes, white blood cell count \(> 50,000 \text{ cells per L} \), lactate \(> 5 \text{ mmol per L} \) or failure to improve on medical therapy after 5 days \([23,38]\). Postoperatively, the patients should continue IV metronidazole or oral vancomycin for a total of 7 days \([39]\).

Although the surgical management of fulminant colitis is similar to that of toxic megacolon, the absence of acute colonic dilatation may permit delay of surgical intervention. Patients who do not begin to respond to the intensive IV steroid regimen should be referred to centers experienced in biologic (infliximab) or cyclosporin therapy in severe colitis, or undergo colectomy \([13,24,25]\).

The type of operation performed for treatment of fulminant colitis or toxic megacolon depends on the clinical status of the patient and the experience of the surgeon \([3,4,16]\). A one-stage procedure that cures ulcerative colitis without the need for a second operation is appropriate for older patients or those not desiring restorative ileal pouch-anal anastomosis. Most surgeons prefer a limited abdominal colectomy with ileostomy, leaving the rectosigmoid as a mucous fistula or the rectum alone, using a Hartmann procedure \([3,13]\). This approach has the advantages of limiting the lengthy pelvic dissection in acutely ill patients while allowing for the option of a subsequent restorative, sphincter-saving procedure (ileoanal anastomosis) \([40]\). In patients with indeterminate colitis or Crohn disease, preservation of the rectum may provide the opportunity for an eventual ileorectal or ileoanal anastomosis to preserve anal continence after temporary diversion and pathologic review of the colectomy specimen.

The surgical management of toxic megacolon must be individualized for each patient. The type of operation selected depends on the clinical condition of the patient and the experience of the surgeon \([3,37,41]\).

Section 20

METABOLISM/NUTRITION

DOMINIC J. NOMPLEGGI
The nutritional management of critically ill patients has changed dramatically over the years. The rationale for nutrition support comes from the knowledge that critically ill patients are prone to developing malnutrition, which is known to be associated with serious complications such as sepsis and pneumonia, leading to poor outcomes and even death \[1\]. In 2009, the Society of Critical Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN) published guidelines offering basic recommendations supported by the review and analysis of the then current literature \[2\]. At that time, these joint societies recommended that the guidelines be updated every 3 to 5 years. The target of the 2016 guidelines is intended to be adult patients, who are critically ill and are expected to require a length of stay, in a medical intensive care unit (ICU) of greater than 2 to 3 days. The current guidelines were expanded to include specific populations including organ failure, acute pancreatitis, and surgical subsets including trauma, traumatic brain injury (TBI), and patients with an open abdomen \[3\]. Based on an expert consensus, the societies recommended that determination of nutritional risk be performed for all patients admitted to the ICU who were not able to consume sufficient calories to meet their caloric requirements. Early enteral nutrition, within 24 to 48 hours, was recommended for all patients determined to be at risk \[3\]. Traditional nutritional indicators or surrogate markers are no longer recommended because they have not been validated in critical care. Indirect calorimetry (IC) should be used to determine energy requirements when available. When IC is not available, the expert consensus of the panel is that a simplistic weight-based equation (25 to 30 kcal/kg/d) be used to determine daily energy requirements \[3\].

Although guidelines continue to evolve, there are sufficient data on clinically proven principles and methods of nutrition support to permit
practical and useful recommendations for the specific problems and questions confronted by the intensivist.

The SCCM and the ASPEN once again conclude that now after more than 30 years of investigation, nutrition support for critically ill patients, once regarded as adjunctive care designed to preserve lean body mass, maintain immune function, and avoid metabolic complications, should now be considered nutrition therapy specifically aimed at attenuating the metabolic responses to stress, prevent oxidative injury, and improve the immune response [3]. Table 212.1 does not list all of the recommendations of the panel but summarizes all the recommendations supported by randomized trials.

**TABLE 212.1 Summary of Evidence-based Guidelines for Nutrition Support**

- EN is preferred over PN for critically ill patients who require nutrition support.
- Bowel sounds are not required for the initiation of enteral feeding.
- Immune modulating enteral formulations should not be used routinely for critically ill patients but may be appropriate for postoperative patients.
- Patients with ARDS and severe acute lung injury should not receive enteral feeding containing anti-inflammatory lipids (i.e., omega-3 fish oil, borage oil) and antioxidants because of conflicting data.
- Antioxidant vitamins and trace minerals, specifically containing selenium, should be given to all critically ill patients receiving nutrition therapy.
- EN regimens not containing glutamine should be reserved for patients with TBI and perioperative patients in the SICU.
- Protocols to promote moderately strict control of serum glucose levels (150–180 mg/dL) when providing nutrition support are recommended.

ARDS, acute respiratory distress syndrome; EN, enteral nutrition; PN, parenteral nutrition; SICU, surgical intensive care unit; TBI, traumatic brain injury.

Adapted from McClave SA, Taylor BE, Martindale RG, et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient: Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) J
WHAT IS MALNUTRITION AND HOW DO WE RECOGNIZE IT?

Malnutrition among ICU patients is common and can be present on admission or develop as a result of the metabolic response to injury. This response to injury can lead to changes in substrate metabolism, causing alterations in body composition and nutrient deficiencies that become clinically evident [4]. During starvation, the body uses fat and muscle protein as a source of energy in order to preserve visceral protein [5]. Mobilization of fat for fuel is an important adaptive response for survival because glucose stores, in the form of glycogen, provide only 1,200 kcal in the first 24 hours of starvation. The body attempts to use muscle protein rather than visceral protein because visceral protein is essential for vital functions of the body. Skeletal muscle mass decreases steadily, and its rate of loss exceeds that of weight loss [6]. Because these changes are difficult to assess, intensivists have traditionally used a variety of tools such as clinical, anthropometric, chemical, and immunologic parameters that reflect altered body composition [7].

Nutritional Assessment

It is not known how long a critically ill patient can tolerate lack of nutrient intake without adverse consequences, but because critical depletion of lean tissue can occur after 14 days of starvation among severely catabolic patients, it is recommended that nutrition support be instituted for patients who are not expected to resume oral feeding for 7 to 10 days [8]. A study conducted by the European Society of Intensive Care Medicine (ESICM) surveyed intensivists from 35 countries using a 49-item questionnaire to determine how they cope with these issues and to assess the current practice of nutritional management in ICUs [9]. In the ESICM study, 45% of the patients were fed within 24 hours and 47% between 24 and 48 hours of admission to the ICU [9].

The need for nutritional support is determined by the balance between endogenous energy reserves of the body and the severity of stress. The best clinical markers of stress are fever, leukocytosis, hypoalbuminemia, and a negative nitrogen balance.

The purpose of nutritional assessment is to identify the type and degree
of malnutrition to devise a rational approach to treatment. Percentage weight loss during the past 6 months, serum albumin level, and total lymphocyte count are readily available, commonly used measures to assess nutritional status. A 10% or 10-lb weight loss over the previous 12 months is an indicator of protein calorie malnutrition. This results from inadequate caloric intake. Hypoalbuminemic malnutrition or kwashiorkor is owing to severe stress or profound malnutrition. Albumin is not a very sensitive indicator of malnutrition among ICU patients because its synthesis is influenced by numerous factors other than nutritional status such as protein-losing states, hepatic function, and acute infection or inflammation [10]. Normal concentrations of albumin are unattainable for many critically ill patients because of large fluid shifts and inadequate synthesis to meet demands. Hypoalbuminemia should be viewed as a marker of injury and not as an indicator of impaired nutrition. Most critically ill patients have a combination of the two. Malnutrition is most effectively treated by nutrition support and treatment of the stresses that led to this severe catabolic condition.

Weight loss of 10 lb or 10% of usual weight is considered clinically important, whereas weight loss of 20% to 30% suggests moderate protein calorie malnutrition and weight loss of greater than 30% suggests severe protein calorie malnutrition. Unfortunately, for many critically ill patients, total body weight is often an insensitive parameter because of progressive total body salt and water retention. The Nutritional Risk Screening 2002 and the nutrition risk in critically ill (NUTRIC) score are the preferred screening and assessment tools because they determine both nutrition status and disease severity [3]. Malnutrition is closely correlated with alterations of immune response as measured by skin test reactivity and total lymphocyte count. A total lymphocyte count less than 1,000 per mm$^3$ is indicative of altered immune function and is associated with decreased skin test reactivity. Loss of delayed cutaneous hypersensitivity to common antigens is a measure of impaired cellular immunity, which has been consistently found to be associated with malnutrition [10].

Subjective global assessment (SGA) is a method for evaluating nutritional status that uses clinical parameters like history, physical findings, and symptoms [11,12]. The SGA determines whether (a) nutritional assimilation has been restricted because of decreased food intake, maldigestion, or malabsorption; (b) any effects of malnutrition on organ function and body composition have occurred; and (c) the patient’s disease process has influenced nutrient requirements. According to the ESICM questionnaire, the critical care community appears to most commonly assess nutritional status using the SGA and laboratory parameters [9]. Current recommendations suggest that these indicators are inaccurate for critically ill patients [3].
HOW MUCH SHOULD YOU FEED?

Macronutrients

Body cell mass is the major determinant of the total caloric requirement. Energy needs can be estimated or measured directly using IC. Although estimated energy requirements have been shown to be adequate in most patients, direct measurement is recommended for patients even when estimating energy needs appears appropriate. Direct measurement is particularly useful in patients who do not appear to respond to therapy (e.g., worsening respiratory function, continued weight loss, or a decrease in prealbumin levels, a more sensitive marker of protein synthesis than albumin).

The general principle of macronutrient support is to provide enough energy to promote anabolic functions and avoid caloric overload. Caloric requirements of 25 to 30 kcal per kg should be based on the usual body weight and are adequate for most patients [3,10]. If patients are not responding to therapy as indicated by the parameters listed previously, or if they are in a severe catabolic state as occurs among multiple trauma or burns patients, the current recommendation is to increase caloric support to up to 35 kcal per kg [3]. However, these recommendations may be changing. A recent meta-analysis of six studies that enrolled 2,517 patients concluded there was no difference in the risk of acquired infection, hospital mortality, length of stay in the ICU, or ventilator-free days among patients receiving an intentional hypocaloric diet as compared to a normocaloric diet [13].

Protein

The usual protein requirement has been estimated to be 1.2 to 1.5 g/kg/d for actual body weight. Another current recommendation by the joint societies is that an ongoing assessment of the adequacy of protein provision be performed. When nitrogen balance studies are not available, weight-based equations (e.g., 1.2 to 2.0 g/kg/d) may be used to monitor adequacy of protein provision by comparing total daily protein calories delivered with that prescribed [3].

Carbohydrates

Generally, patients will need about 25 to 30 kcal/kg/d to meet their energy requirements. Approximately 20 kcal/kg/d of the actual body weight can be provided as carbohydrate. Levels of carbohydrate above 30
kcal/kg/d increase the risk of hyperglycemia. Hyperglycemia should be avoided because it is associated with abnormalities in granulocyte adhesion, chemotaxis, phagocytosis, intracellular killing of pathogens, and poor clinical outcomes.

Hyperglycemia is a major contributing factor to postoperative infections. Blood sugars greater than 220 mg per dL on postoperative day 1 have been associated with a fivefold increased risk of serious infection [14]. A study of patients requiring total parenteral nutrition (TPN) to determine whether the frequency of hyperglycemia and infectious complications can be reduced by an underfeeding strategy (1,000 kcal with 70 g per kg as protein) provision of 1.5 g per kg of protein in conjunction with 25 kcal per kg was not associated with more hyperglycemia or infections than deliberate underfeeding. However, a regimen of 25 kcal per kg in conjunction with 1.5 g per kg of protein did provide significant nutritional benefit in terms of nitrogen balance as compared with hypocaloric TPN [15]. This suggests that it is not a hypocaloric low carbohydrate formula that protects against infection but rather the avoidance of hyperglycemia. Alternatively, TPN can be adjusted and regular insulin can be given, as needed, to maintain a blood glucose level from 150 to 180 mg per dL [3].

---

**Fat**

Usually, no more than 15% to 20% of total calories per day should be provided as fat. This will avoid infectious complications that may be caused by the dysfunction of the reticuloendothelial system, which has been associated with the administration of excess lipids [16]. Omega-6 polyunsaturated fatty acids should be provided in doses adequate to prevent essential fatty acid deficiency (at least 7% of total calories). Medium-chain triglycerides (MCTs) can be administered with long-chain triglycerides (LCTs). MCTs are more water soluble and require less lipase activity and bile salts for absorption. Patients with malabsorption, pancreatic insufficiency, and chronic liver disease can absorb them more easily. The ratio of MCT to LCT depends on the route of administration and product availability [10].

**Electrolytes, Micronutrients, and Fluid**

Potassium, magnesium, phosphate, and zinc should be provided in amounts necessary to maintain normal serum levels. The absolute requirements for vitamins, minerals, and trace elements have not yet
been determined. Normal serum and blood levels of vitamins have been established but may vary with the laboratory in which the measurement is obtained [10]. In general, patients should receive 25 mL of fluid per kg actual dry body weight to avoid dehydration. Three milliliters of trace elements injection 5 (Multitrace-5) and 10 mL of multiple vitamin infusion (Infuvite Adult) will provide adequate vitamins, trace elements, and minerals and should be added to TPN daily. The required daily allowance for all vitamins and minerals is usually provided in 1,000 to 1,500 mL of most enteral formulas. If the patient is receiving less than a liter of enteral feeding, vitamin supplementation may be necessary. Spot electrolyte measurements (aliquots of urine, ostomy, nasogastric, or fistulous output) may be very helpful in determining proper replacement. If the total daily volume of the lost fluid is measured, the daily loss of any electrolyte in that fluid can be estimated using the following equation:

\[ \text{mmol per L} \times \text{volume output per 24 hours (in liters)} = \text{mmol per 24 hours} \]

(e.g., 20 mL of urine contains 100 mmol per L, the daily urine output is 2 L; therefore, the 24-hour urine sodium output is 200 mmol).
WHICH ROUTE OF ADMINISTRATION?

Enteral Feeding

Enteral feeding has been shown in clinical studies to reduce infection and preserve gut integrity, barrier, and immune functions. It is the preferred route of nutrient administration because it is more physiologic, safer, and less expensive than parenteral feeding. Current recommendations support initiation of enteral nutrition as soon as the patient is hemodynamically stable [3]. The only contraindication is a nonfunctioning gut. For example, intragastric feeding requires adequate gastric motility. Gastric residuals should be checked hourly and a volume greater than 500 mL necessitates modification of the infusion rate to minimize reflux and aspiration. Supplemental parenteral nutrition to meet caloric requirements or small bowel feeding to potentially decrease the risk of aspiration will be necessary until normal gastric function returns. Gastric atony and colonic ileus do not preclude enteral feeding but may require gastric decompression or small bowel feeding.

Initiation of enteral feeding does not require active bowel sounds or the passage of flatus or stool. Small bowel feedings can be given in the presence of mild or resolving pancreatitis and low output enterocutaneous fistulas (less than 500 mL per day) [3]. Even patients with severe acute pancreatitis (acute physiology and chronic health evaluation [APACHE II scores 12 to 13] receiving enteral nutrition) have significantly fewer total complications and septic complications than patients receiving parenteral nutrition [17]. A recent study looking at patients with acute pancreatitis (APACHE score of 8 or higher or a modified Glasgow score of 3 or higher) showed no significant differences of rates of major infection, for up to 6 months, among patients fed a nasoenteric diet within 24 hours versus an oral diet initiated at 72 hours [18]. Worsening abdominal distention or diarrhea in excess of 1,000 mL per day requires a medical evaluation. If distention is present, enteral feedings should be discontinued. If no infectious cause for the diarrhea is found, antidiarrheals can be administered and feedings continued [10]. Nasogastric feeding is appropriate for most patients except those with a history of aspiration pneumonia associated with reflux. Those patients should be fed postpylorically or via a G-tube to minimize nasogastric tube-associated reflux of gastric contents and aspiration. In contrast to prior recommendations, the ASPEN/SCCM guidelines now recommend that patients with severe acute pancreatitis can be fed by either the gastric or the jejunal route because there is no difference in tolerance or clinical outcomes [3]. A study of four university-based ICUs at two
hospitals found that physicians ordered a daily volume of enteral feeding that was 66% of the requirement; but because only 78% of the ordered volume was infused, patients received only 52% of target calories. Sixty-six percent of the time the reasons given for stopping the infusion were determined to be avoidable. Half the patients whose tube feedings were checked every 4 hours had their feedings held for residual volumes less than 200 mL, when the guideline for stopping the tube feeding was a residual of greater than 200 mL [19]. Protocols for delivery of enteral feeding can avoid this.

Standard isotonic polymeric formulations can meet most patients’ nutritional needs. The use of elemental formulas should be reserved for patients with severe small bowel absorptive dysfunction. The “American Gastroenterological Association Medical Position Statement: Guidelines for the use of enteral nutrition” and the current ASPEN/SCCM have concluded that disease- or organ-specific specialty formulations are generally more expensive and have a limited clinical role, and they will require more data to justify their practicality and effectiveness. Immune modulating formulations containing arginine and fish oils can be considered for patients with severe trauma [3,20].

There are numerous issues that arise when providing enteral nutrition to critically ill patients. We provide guidelines to help the readers of this chapter overcome the problems that often arise when administering enteral tube feedings.

In general, most complications associated with the use of feeding tubes relate to placement, displacement, or malfunction of the tubes. It is important to remember that these tubes require frequent maintenance to avoid complications. The position of nasogastric or nasoenteric feeding tubes placed at the bedside should be confirmed endoscopically or radiographically before use because clinical assessment is unreliable. The routine use of promotility drugs has not been shown to be consistently beneficial and although they can increase the volume of feeding, the overall impact is small except for patients at high risk of aspiration [3]. Excessive force during insertion, which can result in malposition, should be avoided. Tubes need to be flushed regularly to avoid clogging with medications or tube feeding. Cycled tube feeding is recommended, if possible, to facilitate this. Little is known about the compatibility of most medications with tube feeding and, therefore, medications should not be mixed with tube feedings because this can lead to precipitation of the medication with blockage of the tube and decreased absorption of the medication.
Placement of tubes across the gastroesophageal junction or pylorus can lead to incompetence of the sphincter, reflux, and aspiration. In patients at risk for or with a history of aspiration associated with reflux, we recommend percutaneously placed gastric or jejunal feeding tubes. Gastric tubes are preferred because the smaller caliber of the jejunal tubes makes them likely to obstruct with administration of anything except liquid medications. Percutaneously placed tubes that fall or are pulled out should be replaced cautiously. Unlike noncritically ill patients who usually have had their feeding tubes in place long term, critically ill patients are likely to have had their tube placed recently or may have impaired healing and, therefore, may not have a fully developed cutaneous fistula. For these reasons, we recommend confirming placement with a contrast-enhanced radiograph before use when replacing these tubes at the bedside.

Elevating the head of the bed 30° and checking for gastric residuals to avoid increases in the volume of the gastric contents, which can lead to hypersecretion and reflux of gastric contents, are also recommended.

Stress gastritis, also known as stress-related erosive syndrome, is a term used to describe gastrointestinal mucosal injury associated with serious systemic disease. Most patients at risk cannot have oral feedings. Histamine H\textsubscript{2} receptor antagonists (H\textsubscript{2}RAs) have been shown to protect against significant gastrointestinal hemorrhage. There are less data on the efficacy of proton pump inhibitors (PPIs). A reasonable suggestion has been to wait for 6 to 12 hours between stopping parenteral H\textsubscript{2}RAs before starting to feed and initiating therapy with a PPI [21].

Parenteral Feeding

Parenteral nutrient administration is recommended when the gastrointestinal tract is nonfunctional or inaccessible or enteral feeding is insufficient. Although parenteral nutrient admixtures are not as nutritionally complete as enteral formulations, nutritional goals are achieved more often with the former than the latter. This is usually attributable to a variety of barriers. In patients determined to be at high nutritional risk or severely malnourished, when enteral nutrition is not feasible parenteral nutrition should be initiated as soon as possible. In addition, if patients at high risk do not meet greater than 60% of energy and protein requirements by the enteral route, supplemental parenteral nutrition should be initiated [3].

Parenteral nutrition is associated with an increased risk of infectious complications, especially line infections, and increased costs. Strict adherence to protocols emphasizing aseptic techniques and limiting central line interruption can decrease complications. Peripheral indwelling central catheters or central subclavian or internal jugular lines
should be considered, and implanted permanent lines should be avoided [10]. Management of infected temporary lines is easier and has fewer complications.
HOW DO YOU PREVENT COMPLICATIONS AND MAXIMIZE BENEFITS?

Anticipating potential complications leads to early recognition, minimizes the impact of the complications, and improves outcomes. Adherence to general guidelines for energy requirements, as mentioned earlier, should help avoid overfeeding. Overfeeding can lead to a number of problems, such as cholestatic liver disease, hyperglycemia, increased infection risk, and worsening hypercapnic respiratory failure. When there is doubt, expired gas analysis can be used to assess caloric requirements. A respiratory quotient (R/Q) greater than 1 generally indicates overfeeding. R/Q is the quotient of mL of CO$_2$ produced per mL of O$_2$ consumed. Increased CO$_2$ production will cause a rise in the R/Q from 0.80, a normal, average steady state. Reducing total calories (glucose and fat) may benefit patients with chronic lung disease fed parenterally who develop worsening hypercapnia. Assessment of nitrogen balance (the difference between nitrogen produced and nitrogen eliminated in urine and stool) every 5 to 7 days may be useful for assessing the response to adjustments of the protein dose. Prerenal azotemia from excessive protein administration is an indication to decrease nitrogen intake. Patient outcome following acute renal failure (creatinine greater than twice normal) does not improve with the administration of specialized formulations.

Monitoring triglycerides and adjusting continuous fat infusion to keep triglycerides less than 500 mg per dL will avoid hypertriglyceridemia. Monitoring of prealbumin because of its short half-life (i.e., 2 days) can be used to assess response to feeding in the ICU setting. Monitoring of fluid and electrolytes is essential particularly in patients receiving TPN to avoid volume overload. Deficiencies of potassium or calcium can lead to cardiac arrhythmias. Hypophosphatemia can precipitate rhabdomyolysis, severe muscle weakness, and respiratory failure. Hypomagnesemia can cause muscle weakness and even seizures. Zinc deficiency can lead to impaired wound healing, diarrhea, and cutaneous anergy. Routine monitoring of vitamins and minerals for patients on short-term parenteral nutrition support is not useful because deficiencies are usually only associated with long-term therapy. Monitoring on a selected case basis when there are clinical signs or symptoms of a vitamin deficiency (e.g., hyperkeratosis [vitamin A], megaloblastic anemia [folate/vitamin B$_{12}$]) is more practical. Liver enzymes should be monitored weekly to determine if biliary or liver disease has developed [10].
WHAT IS THE IMPORTANCE OF PROVIDING SPECIAL KEY NUTRIENTS?

Effects of special nutrients on regulation of the processes of inflammation and repair and immune function have been the object of many studies. Although specialized nutrients added to parenteral or enteral formulas have been shown to modulate a variety of cellular responses, their precise clinical utility is still unresolved. For example, arginine is an amino acid that participates in a variety of metabolic processes, including synthesis of nitrous and nitric oxide, compounds known to protect the liver from damage in a murine model of endotoxin-induced hepatic necrosis [22], urea synthesis, lymphocyte proliferation, and wound healing. Other studies have shown that diets rich in fish oils increased the survival of guinea pigs challenged with endotoxin [23,24].

The branched chain amino acids leucine, isoleucine, and valine are essential amino acids required for protein synthesis. Although improvement in nitrogen balance can be observed when these are given in combination with other essential amino acids in doses of 0.5 to 1.2 g/kg/d, their efficacy in improving patient outcomes remains to be defined and their use is not recommended [3,25].

The importance of glutamine to normal cellular function and its unique function in amino acid metabolism, in both health and disease, has been recognized for many years [26]. The skeletal muscle-free amino acid pool is 61% glutamine, and accelerated mobilization of glutamine occurs during catabolic states. In such states, glutamine depletion occurs despite administration of standard parenteral amino acids, which do not contain glutamine because of their instability in aqueous solution. In rats, decline of the intracellular pool of glutamine in the skeletal muscle has been shown to correlate with skeletal muscle protein degradation. The majority of glutamine released from skeletal muscle is taken up by intestinal cells. Rat studies have shown that glutamine-supplemented parenteral nutrition improves gut mucosal metabolism and nitrogen balance during sepsis and also increases villus height and mucosal thickness in starved rats, suggesting that mucosal barrier defense is improved [27,28]. However, in humans, a randomized trial of glutamine supplementation of parenteral nutrition detected no difference in infectious complications or median length of hospital stay between
groups and their routine use is not recommended [3,29].

Addition of specialized key nutrients to enteral formulas to enhance immune function has been suggested for the reasons outlined earlier. A meta-analysis of 12 studies that used either of the two most common commercially available enteral feeding preparations enriched with the “immunonutrients” arginine and omega-3 fatty acids concluded that they had no effect on mortality [30]. However, significant reductions in infection rates, ventilator days, and length of stay in hospitals in patients fed these formulas were most pronounced among surgical patients [30]. Although the relative efficacy of any single immune-enhancing component versus its combination with another is impossible to state on the basis of the presently available evidence [31], commercially available formulas fortified with “immunonutrients” may be beneficial, but their routine use in medical ICUs is not recommended [3]. Rather, these formulations should be reserved for patients with TBI and in postoperative patients in surgical ICUs [3].

Although the administration of growth hormone can attenuate the severe catabolic state induced by the metabolic response to injury, surgery, and sepsis, two randomized placebo-controlled clinical trials found that in-hospital mortality, length of stay in the ICU, and duration of mechanical ventilation were greater among patients receiving growth hormone [32].

In summary, nutritional support should be considered essential for the treatment of prolonged critical illness. We have provided some useful guidelines for nutritional assessment, estimation of energy requirement, route of nutrient delivery, estimations of the effectiveness of nutrition provided to critically ill patients, and also suggested some practical points to simplify delivery and avoid associated complications related to parenteral and enteral feeding.
REFERENCES

Nutritional and metabolic support during acute illness is an integral part of the clinical care of critically ill patients. The significance of such interventions is predicated on three main factors: (a) degree of metabolic stress; (b) dysfunction of major organ systems; and/or (c) presence of protein-calorie malnutrition (PCM). In the first case, metabolic stress can arise from a variety of sources, including, for example, severe injuries sustained by major trauma such as closed head injury, multiple long-bone fractures, third-degree burns of greater than 25% of body surface area, or severe sepsis and stress of lesser intensity such as thoracoabdominal surgery, pulmonary infection, systemic infection, or any source of active systemic inflammation. Often, more than one form of metabolic stress may be present that can accentuate and/or dysregulate the injury response. Concerning the second factor, metabolically stressed patients may develop acute failure of vital organs during the critical care period or have underlying chronic end-organ dysfunction. Acute or chronic disease, particularly of the cardiopulmonary, renal, or hepatic system, often further complicates the clinical course and requires modification of nutritional support during critical illness, especially among the elderly [1]. Finally, the presence of preexisting or the likely early development of PCM is the key to identifying patients who will derive the greatest clinical benefits from nutritional and metabolic support therapies.

Approximately 35 years ago, the prevalence of PCM among hospitalized general medical and surgical patients was reported to be as high as 50% of all adult admissions to a large teaching hospital [2,3]. More recent reports continue to document high rates of malnutrition among hospitalized patients [4–9]. When moderate to severe PCM
accompanies severe metabolic stress, an increase in nutrition-related complications can be expected to occur, including wound dehiscence, nosocomial infections, and severe fluid, electrolyte, and acid–base disturbances. During stress, substantial catabolism of both endogenous and exogenous protein and energy occurs coincident with the injury response. For support of the metabolic response to injury, the breakdown of body protein, principally from muscle and connective tissue stores, supports amino acid and energy needs to mount various beneficial components of the systemic inflammatory response by the release of amino acids for accelerated synthesis of proteins and cells, including leukocytes, hepatic acute phase and cellular proteins for wound repair, and gluconeogenesis. The goal is to optimize energy requirements for metabolically active tissues, including cardiac myocytes, leukocytes, and fibroblasts. An assessment of the degree of this response can be estimated by application of the catabolic index (CI) [10]. However, if PCM complicates injury or infection, the systemic inflammatory response is less intense than that found in normally nourished individuals with a similar degree of injury. Consequently, the degree and duration of the metabolic response, with respect to nitrogen breakdown, may be greatly diminished. In terms of the degree of catabolism, for example, a malnourished elderly patient with significant catabolic injury could manifest nitrogen losses that may be as a much as 50% less than normally nourished younger counterparts with the same injury [1]. Although this might imply a less severe catabolic response sparing lean tissue, the pathologic consequences are more severe as a result of the muting of the beneficial aspects of the systemic inflammatory response, and these adverse effects tend to occur sooner. Moreover, the time course to intervene with nutritional and metabolic support to limit the likelihood of nutrition-related complications is also shortened by as a much as 50% (i.e., 5 to 7 days) in the moderately to severely malnourished versus normally nourished individuals (i.e., 7 to 10 days) with the same metabolic stress. Ultimately, the consequences of ongoing depletion of the metabolically active body cell mass of the malnourished reduce the ability to recover from acute illness, can be associated with severe deficiencies of minerals that are typically found in muscle (potassium, magnesium, and phosphorus), and often lead to severe impairments in immunocompetence, wound healing, and recovery of organ function.

Once the decision to provide nutrition support is made, parenteral nutritional (PN) or enteral nutritional (EN) therapies are available options. In nearly every case, if the gastrointestinal (GI) tract is functional and the patient is hemodynamically stable, EN should be instituted. However, if significant malnutrition also exists and a prolonged recovery is anticipated, it should be recognized that the time frame to achieve eucaloric intakes for EN often takes much longer
because of the associated GI intolerance, compared with PN. Because central venous access is generally necessary during critical illness, EN support can often be supplemented with PN [11] so as to avoid the prolongation of caloric deficits during acute illness, which are particularly of concern for initially malnourished patients or for the most severe critically ill with closed head injury, multiple trauma, major burns, and severe sepsis. For such patients, it appears that early feeding within the first 72 hours, whether by enteral, parenteral, or the combination, has the greatest impact on mortality outcomes. Although mild decrements in energy balance in the critical care setting may well be tolerated and, in certain circumstances, appropriate, at least 1 g of protein per kg and 15 kcal per kg advancing to 1.5 g protein per kg and 20 to 25 kcal per kg in the second week of injury should be the goal to avoid adverse, nutrition-related outcomes. Moreover, intensive metabolic support (i.e., the provision of electrolytes and acid–base therapy) can also be accomplished efficiently through the PN admixture. The amount of PNs can be gradually reduced because the patient is transitioned to EN coincident with remission of the stress response and return of full GI tolerance to tube feeding. Thus, in the intensive care unit (ICU), nutrition support is often provided to patients using both enteral and parenteral means, especially during the acute care period. The purpose of supplying both EN and PN where appropriate should not be motivated by attempts to meet protein and energy needs as soon as possible, but rather as a means of providing trophic stimulation to enterocytes and hopefully a quicker transition to full enteral feedings, while PN is used to treat severe metabolic disorders such as hypokalemia, hypophosphatemia, and metabolic alkalosis, that can only be safely and effectively addressed by the intravenous route of administration. The greatest challenge facing the critical care clinician is to appropriately identify those patients who are in greatest need of nutrition support therapy and to provide it in a manner that is both effective and does not produce iatrogenic complications.

CLINICAL CONSEQUENCES OF DELAYING NUTRITIONAL SUPPORT

Although, at times, it is difficult to pinpoint the cause and effect of nutrition-related complications during critical illness, it should be intuitively obvious that withholding nutrition will ultimately lead to death from starvation. This message was poignantly illustrated in the deaths of
Maze prisoners in Belfast, Ireland, as detailed in a report from Leiter and Marliss [12] in 1982. Ten Irish Republican Army prisoners went on a hunger strike that led to their deaths over a period of 45 to 73 days of fasting. All were young lean males, and the critical weight loss that resulted in death was approximately 35% calculated from the first day of the fast. It is also generally acknowledged that patients who approach 35% to 40% losses from their ideal or usual body weight through inadequate nutritional intake are at greatest risk of malnutrition-related death. Presumably, at these extreme levels of body mass depletion, both the size and function of vital organs of the viscera are considerably diminished. At some critical point, presumed to be when fat stores become limited, protein catabolism now coming from both skeletal and visceral organs accelerates. If one discontinues providing life-sustaining needs for energy, the loss of a critical mass of body protein is ultimately reached and death from organ failure is imminent.

The effects on the vital organ function can be catastrophic, because oxygen consumption of the visceral organs is much higher than that of resting skeletal muscle. The imbalance between loss of skeletal muscle and visceral organ mass initially favoring visceral organs has also been suggested to explain the higher energy expenditures per body weight seen in severely depleted hospitalized patients (average of approximately 70% of ideal body weight [IBW]) as a result of an approximate 10-fold difference in resting oxygen consumption between skeletal muscle compared to visceral tissues such as the liver [13]. During starvation (with adequate water intake), and in the absence of metabolic stress, a normally nourished, thin individual can survive for periods of approximately 6 to 10 weeks. In terms of total body nitrogen, it is estimated that the loss of 350 to 500 g of nitrogen is potentially lethal. In terms of body mass index (BMI), which is weight in kilogram per height in meters squared, it is generally considered that a BMI less than 13 kg per m² in males and less than 11 kg per m² in females is incompatible with life [14]. However, the rapidity of weight loss is also a factor, because lesser degrees of semistarvation (i.e., smaller energy deficits) are better tolerated. Table 213.1 depicts the relationship of BMI with nutritional status.

By way of comparison, the metabolically stressed patient experiences greater catabolism coincident with acute illness and can lose as much as 30 g of nitrogen per day, representing about 1 kg of lean tissue from the breakdown of lean body mass. Generally, the majority of these losses can be measured in a 24-hour urine collection as urea nitrogen and used for nitrogen balance estimation. Nitrogen balance studies assess the difference between dietary protein (nitrogen) intake and nitrogen excretion. Healthy individuals consuming an adequate diet in terms of essential nutrients, including protein (0.8 g protein/kg/d) and sufficient energy to provide energy balance, will be in zero nitrogen balance. That is, the nitrogen in is equaled by the nitrogen out in urine (mostly) and feces, reflecting no net change in lean body mass. Net nitrogen losses for patients receiving parenteral or enteral feeding can vary from 0 to 30 g per day, depending on the extent of the injury response and the level of feeding. With the systemic inflammatory response, the utilization of protein to maintain lean body mass is impaired, making the daily requirement increase to about 1.5 g protein/kg/d. Similarly, energy requirements increase, which are offset to some degree by the reduction of physical activity characteristic of the hospitalized patient. With the development of renal dysfunction, the proportionate amounts of nitrogen found in the urine become substantially less, with a concomitant rise in blood urea nitrogen (BUN). In general, in a 70-kg male, every 5 mg% change in BUN represents 2 g of nitrogen catabolized and not excreted, and 1.5 g of nitrogen for a 60-kg female, based on average total body water (TBW) of 60% and 50% for males and females, respectively. Protein intakes must be adjusted to limit the rise in BUN, but nutrition efficacy should not be sacrificed to renal function beyond a reduction to the 1 g protein per kg for other than very brief periods. Renal replacement therapy such as dialysis or hemofiltration should be considered in those circumstances. Once the BUN becomes stable, even if elevated by impaired renal function, a 24-hour urine urea nitrogen excretion represents the amount catabolized over that period. The CI (CI = 24-hour urine urea nitrogen – [0.5 × dietary nitrogen + 3]), adjusts for the effects of dietary intake and obligatory nitrogen loss on urinary urea nitrogen.
excretion. The CI is the difference between measured and predicted urine urea nitrogen excretion. For example, the major catabolic stresses that produce the highest nitrogen losses and CIs include burns, head injury, severe sepsis, and multiple trauma. The clinical application of nitrogen balance and CI assessments are illustrated in Table 213.2.

### Table 213.2 Clinical Application of the Nitrogen Balance and Catabolic Index Assessments

| Nitrogen balance | = protein intake (g) 6.25 \(-\) (24 h UUN + 4)  
|                  | = 105 (g) 6.25 \(-\) (20 + 4)  
|                  | = –7.2 g  
| Catabolic index  | = UUN (g) \(-\) (½ \times\) dietary nitrogen + 3  
| (<0 no significant stress; 0–5 significant stress; >5 severe stress) | = 20 g \(-\) (0.5 \times\) 16.8 g + 3  
|                  | = 8.6 (severe stress)  

Assumptions: 70-kg male; 105 g protein intake; 20 g UUN over 24 hours. UUN, urine urea nitrogen.

There are potential clinical scenarios that may affect the accuracy of nitrogen balance studies. This is especially true for patients with renal dysfunction that may reduce nitrogen output and could erroneously suggest an improvement in nitrogen balance. A correction of the nitrogen balance study can be applied to account for the nitrogen losses that do not appear in the urine, but result in an increase in the BUN concentration. Assuming nitrogen intake remains constant, two important pieces of data are required to correct for the nitrogen losses not appearing in the urine and include the patient’s BUN and body weight at the beginning and end of the 24-hour collection period. These are important because most of the urea is distributed in TBW. A clinical example that applies to this method of correction appears in Table 213.3.
In terms of lean body mass, each gram of nitrogen lost represents approximately 30 g of (hydrated) lean tissue (hydration ratio: approximately 4:1 or 5:1). For patients with daily nitrogen losses of 30 g, which represents the highest catabolic nitrogen loss in the absence of dietary protein intake, approximately 1 kg of lean tissue would be lost each day. Such losses cannot be sustained for protracted periods, and, under these circumstances, nutrition support is clearly indicated within the first 24 to 36 hours even in the previously well-nourished patient to
address this extraordinary rate of loss. Using cumulative nitrogen deficits of 350 to 500 g, a sustained loss of this magnitude could theoretically result in death in approximately 2 to 3 weeks, although catabolic rates usually diminish in the later weeks of injury. For the severely malnourished patient of 75% of IBW, one can estimate the critical survival period to be in the range of 1.5 to 2 weeks under the same circumstances. Finally, a cumulative caloric deficit of 10,000 kcal or more during acute illness has been associated with significant morbidity and mortality among surgical ICU patients [15]. However, it is likely that the associated protein deficit played the larger role, because normal individuals have more than 150,000 stored calories as fat, which always makes up the greater proportion of the caloric deficit. A study in the medical ICU has shown that intakes of less than 25% of requirements were associated with a higher rate of bloodstream infections [16].

Of course, projections of survival or complications are estimates and may be highly variable depending on other factors, including nutritional status, metabolic stress, and end-organ function. Moreover, in the clinical setting, such high outputs of nitrogen over long periods will not likely be sustained, because medical and surgical therapies will usually successfully reduce the stress response. Furthermore, both the rate of reduction of lean body mass and the intensity of the systemic inflammatory response diminish as PCM develops. Such patients will invariably receive calories (dextrose) and electrolytes from various parenteral infusions, so that some form of supplementation is given, which also slows the loss of lean tissue. Consequently, the outcome of death from the total lack of nutritional support is rare. However, nutrition-related complications, such as impaired wound healing and immunocompetence leading to nosocomial infections, are the common proximate causes of increased morbidity and mortality under such circumstances.
IDENTIFYING PATIENTS IN NEED OF NUTRITIONAL SUPPORT

In the ICU setting, it is often difficult to identify those patients who are at greatest risk of developing nutrition-related complications because of preexisting malnutrition. Such patients are often volume overloaded because of massive administration of parenteral fluids from multiple drug therapies and often acute volume resuscitation, as well as maintenance intravenous therapy to support intravascular volume. This fluid retention and weight gain is often compounded by the hormonal consequences of the systemic inflammatory response such as enhanced insulin, aldosterone, and antidiuretic hormone secretion, which favor salt and water retention. Consequently, the weight of the patient is artificially high, and major efforts of the ICU team are often directed at reducing volume intake in order to mobilize third-space fluids. A weight history may be difficult to obtain or overlooked entirely because of more acute clinical issues. Moreover, an accurate patient weight is also important to optimize drug therapy. Under these circumstances, a moderately to severely malnourished patient may escape detection by the primary care team, and only be recognized as malnourished after fluid homeostasis is achieved, or worse, a potentially preventable nutrition-related complication, such as wound breakdown, occurs. Clearly, at this point, the opportunity to minimize such complications from expert nutrition support has passed, and the course toward rehabilitation may be long and costly.

To avoid this scenario, a more substantial effort must be undertaken to identify the patients who are at greatest risk. Nutrition screening programs on admission, especially by dieticians, can greatly assist in identifying these patients, but some patients, especially admissions for emergent care, may escape this surveillance process. In these cases, the premorbid weight is very important and should be obtained if at all possible. It will at least provide a baseline prior to the numerous medical and surgical maneuvers that may take place over the ensuing 24 to 48 hours that could dramatically change the patient’s weight in the critical care setting.

If the admission weight is not obtained, then the clinician may need to estimate the patient’s body weight from available hospital data.
Estimations may be made based on the most recent weight recorded and then backtracked through the medical chart using the intake and output records to reconstruct the original weight history. For critically ill patients, such records are usually reliable, and a reasonable estimate may be made. This estimate may be confirmed by subsequent discussions with the patient or family. When confirmed, the body weight can then be compared to standard measures for population-based body weight for height tables, such as the IBW or the BMI. A patient weight less than 85% of IBW or BMI less than 18.5 indicates moderate malnutrition. Severe malnutrition would be considered likely if weight is less than 75% of IBW or BMI is less than 16 kg per m². Thus, a greater sense of urgency to intervene with nutrition support is present under these conditions and should be undertaken within several days of the acute injury. If the patient is deemed well nourished, then intervention may be delayed unless the systemic inflammatory response is severe (i.e., major third-degree burns, closed head injury with a Glasgow Coma Score less than 8, multiple trauma with very high acute physiology and chronic health evaluation [APACHE] or injury severity scores, or severe pancreatitis with a positive computed tomography scan and more than three Ranson criteria. Then, because the systemic inflammatory response is likely to endure beyond 1 week, very early nutritional support is indicated. The serum albumin level, which reflects the presence of a recent systemic inflammatory response, is not often helpful in this setting because the invariable systemic inflammatory response and common disturbances in volume status make hypoalbuminemia universal. However, severe hypoalbuminemia (less than 2.4 g per dL) usually reflecting a greater degree and/or longer duration of systemic inflammation identifies a population at much greater nutritional risk. Finally, if the weight-based data are not reliable, a formal nutrition support consult or indirect calorimetry may be indicated.
NUTRITIONAL REQUIREMENTS

Protein

The amount and type of protein administered to the critically ill depends on the clinical circumstances of each patient. Nevertheless, there is an upper limit to the quantity of protein that can be given based on net protein utilization during metabolic stress. In general, providing protein in amounts above 1.75 g/kg/d exceeds the capacity of the body to use the administered protein to increase synthesis [17,18]. Amounts above this level of intake are essentially completely converted to urea and serve no nutritional purpose. At intakes ranging between 0.6 to 1.75 g/kg/d, each increment of intake increases net protein synthesis at a cost of increasing the proportion going to ureagenesis. In patients with nitrogen accumulation disorders (of either renal or hepatic origin), a compromise must often be made between greatest rates of net protein synthesis and lowest rates of urea or ammoniagenesis. For example, as the BUN increases, especially above 100 mg%, the risk of uremic complications increases, including bleeding, or, increasing the production of ammonia in encephalopathic patients. Generally, the optimal protein intake in critically ill patients is given at twice the recommended daily amount (approximately 0.8 g/kg/d) of normal adults, at approximately 1.5 g/kg/d. With renal impairment, at least 1 g per kg should be provided and greater amounts given if tolerated or dialysis is initiated. For patients with liver failure, at least 1 g per kg of standard protein should be provided and up to 1.5 g per kg if tolerated. This is done recognizing the overall impairments in protein utilization that accompanies metabolic stress, as well as the heightened needs during catabolism.

The type of protein administered varies with the patient’s condition and the route of administration. For PN support, standard protein mixtures are given in their monomeric form as individual crystalline amino acids and levorotatory isomers, which comprise the essential amino acids (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine) and the nonessential amino acids (alanine, aminoacetic acid, arginine, cysteine, proline, serine, and tyrosine). In standard amino acid formulations, the branched-chain amino acids (leucine, isoleucine, and valine) comprise approximately 18% to 25% of the amino acid profile. Collectively, they are available in commercial intravenous solutions in concentrations ranging from 3% to 15%. On average, for every 6.25 g of the amino acids in the mixture, 1 g of nitrogen is available, although this number is lower with a number of the specialized amino acid formulas. The caloric value of
protein is 4.1 kcal per g, and such calories should be counted in critically ill patients when tracking energy intakes.

Specialized amino acid mixtures have evolved that include selected profiles. For example, renal formulations have been devised that principally provide the essential amino acids (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine), whereas hepatic formulations have eliminated or reduced aromatic amino acids (phenylalanine, tryptophan, and tyrosine) and the sulfur-containing amino acid methionine and increased the proportion of branched-chain amino acids (isoleucine, leucine, and valine). However, the routine use of these expensive formulations for these conditions over conventional or standard amino acid mixtures has not been convincingly demonstrated and, in certain cases when used to meet full protein needs, may be harmful [19]. For patients with nitrogen accumulation disorders, the use of branched-chain–enriched amino acid formulas in the range of 45% to 50% of the total amino acid profile has been shown to improve protein utilization when total amino acid intakes are given in the 40- to 70-g range and may reduce the risk of encephalopathy when compared to a standard formula. Finally, other attempts at modifying the profiles of amino acid mixtures, such as the extemporaneous preparation by the hospital pharmacy of sterile glutamine in total parenteral nutrition (TPN), have shown some benefits in selected settings, but they require a considerable level of parenteral compounding expertise. In addition, in order to safely provide this compounded sterile preparation, ongoing quality assurance measures as outlined by the United States Pharmacopeia (USP) must be performed and, therefore, such practices are subject to the Federal Drug Administration oversight [20]. A glutamine-containing dipeptide formulation, which is commercially available in Europe, has been the subject of some positive trials, but its ultimate place in the care of the critically ill is not yet established. In a recent review of the evidence, however, the safety of glutamine supplementation, when given in pharmacologic doses, has been raised, and caution is advised at this time with respect to its indiscriminant use in the ICU [21].

For EN support, protein is typically provided in either an oligomeric form as protein hydrolysates containing various peptides ranging from di- and tripeptides to polymers of eight or more, or as whole protein usually provided as casein or in its polymeric form as, for example, casein hydrolysates. Less commonly, they can even be provided as the individual amino acids. Most formulations contain a fixed amount of protein in the range of 30 to 40 g per L and thus for fluid-restricted patients in the ICU cannot meet the protein needs of most patients. Alternatively, more concentrated enteral formulas exist that may be used, or the clinician may opt to add protein modules to conventional products to increase
protein density. However, in either case, both approaches result in higher osmolarities that may affect GI tolerance.

Carbohydrate

The amount and type of energy provided to improve the utilization of the prescribed protein intake also varies with the individual patient. As well, there are physiologic limits to the amounts given, beyond which significant complications are more likely. For most patients, providing 25 kcal/kg/d is sufficient to support the protein synthetic response to metabolic stress. This is the total energy expenditure of most critically ill, postoperative patients. Amounts above 30 kcal/kg/d exceed the energy expenditure of most hospitalized patients except those with severe burns, closed head injury, and multiple trauma where measured caloric expenditures are usually 30 to 40 kcal per kg. However, providing nutritional support in amounts greater than 30 kcal per kg leads to higher rates of hyperglycemia in both types of patients: in the postoperative setting, because of overfeeding, and in the trauma unit, because of the severity of systemic inflammatory response. Although better glycemic control through the use of insulin would be one way to reduce the infectious risk in the latter instance, it is interesting to note that in several trials of immune-enhancing diets that improved outcomes and reduced infection rates have been seen at energy intakes at 30 kcal per kg or less, in diets that are likely to have been hypocaloric [22]. For carbohydrates, the physiologic limits are linked to the normal endogenous hepatic production rates for glucose, which approximate 2 mg/kg/min or about 200 g per day for a 70-kg healthy adult [23]. This is the amount of glucose needed by the body to meet the obligate needs of tissues dependent on glucose (i.e., brain, renal medulla, red blood cells), and it is derived from body stores of glycogen (glycogenolysis) or made from noncarbohydrate sources such as from protein breakdown to gluconeogenic amino acid precursors (gluconeogenesis). Glycogen stores are limited and, therefore, can be rapidly depleted during acute metabolic stress (i.e., within 24 hours) [24]. Thus, the major source of glucose in the hypocaloric state following stress comes from gluconeogenesis, and higher-than-usual amounts are produced to support the metabolic response to injury, accelerated by the hormonal milieu produced by the increased secretion of catecholamines, glucagon, cortisol, and growth hormone [25]. The judicious provision of nutritional support is designed to attenuate the extent of protein breakdown without exacerbating significant changes in nutritional and metabolic homeostasis. Similar to
the case with protein, as carbohydrate intake increases, net oxidation occurs, but with an increasing proportion going to nonoxidative pathways (glycogen synthesis and particularly de novo lipogenesis). However, glycogen synthesis is limited by available storage capacity of about 500 g in normal adults and perhaps 1,000 g in a critically ill patient receiving TPN, with its resultant very high insulin levels. There is effectively no limit for fat storage. The optimal balance is at intakes at about 400 g per day, with maximal glucose oxidized of 700 g per day. Thus, in a 70-kg adult, glucose to amino acid ratio of 2:1 TPN formula providing 400 g per day of glucose and 1.5 g of protein/kg/d represents about 25 kcal/kg/d.

For PN, glucose is the only reasonable carbohydrate fuel or energy source that is widely available for intravenous administration. Generally, it is provided as a monohydrate, and its caloric equivalent is, therefore, 3.4 kcal per g rather than 4 kcal per g for its anhydrous form. It is commercially available in a variety of concentrations ranging from 2.5% to 70% in sterile water for injection. Glucose is the primary energy source of any PN admixture prescribed for central venous alimentation and typically is given in final admixture concentrations from 10% to 25%. Higher concentrations can be given, but are associated with an increase in the number of dextrose-associated complications if the amounts given are too large.

For EN, carbohydrates may be given in a number of chemical forms. For example, they can be given as the monosaccharide, glucose, frequently found in monomeric or elemental formulas. Alternatively, in less refined formulas, carbohydrates may be provided as oligosaccharides, such as hydrolyzed cornstarch, or more complex polysaccharides, such as corn syrup, are frequently used. The selection of a particular enteral formula is largely based on a number of clinical factors, such as GI function, fluid status, and end-organ function.

**Fat**

Lipids serve as an alternative energy source that is used to substitute for a portion of the carbohydrate calories. PN support prescribed in this fashion, it is referred to as a total nutrient admixture, all-in-one or three-in-one mixed-fuel system [26]. As with protein and carbohydrates, the amount and type of lipids used will vary depending on the clinical condition of the patient. For the most part, long-chain triglycerides (LCTs) derived from vegetable oils have been the principal source of lipid calories used in the clinical setting. Specifically, soybean oil, which is rich in polyunsaturated ω-6 fatty acids, has been extensively used, especially for intravenous nutrition. It is a major source of the proximate essential fatty acids, linoleic, and α-linolenic acids. However, ill-considered prescribing habits, where either excessive quantities or infusion rates
have been used, have led to clinically significant adverse effects such as immune dysfunction and pulmonary gas diffusion abnormalities among critically ill patients. The excessive administration of intravenous lipid emulsions (IVLEs) can accumulate in the liver and impair Kupffer cell function, thus interfering with a major component of the reticuloendothelial system [27,28]. In addition, lipid injectable emulsions are composed of various oils that serve as prostaglandin precursors that are immunosuppressive, especially those of the n6 series such as PGE₂, which suppresses lymphocyte proliferation and natural killer cell activity [29], and can reverse hypoxic vasoconstriction in patients with adult respiratory distress syndrome [30]. In contrast, the oxidation and subsequent plasma clearance of lipids are significantly improved when IVLEs are given over 24 hours versus briefer intervals [30]. Impaired plasma clearance of lipids can result in fat overload syndrome and is a particularly significant clinical issue in children [31–42]. Fat overload syndrome can result from the administration of a stable fat emulsion over brief intervals [30,43–48] or from more modest doses of lipid that might be physicochemically unstable [49]. In fact, a review of the literature regarding stable fat emulsions has concluded that virtually all of the adverse effects associated with LCTs have occurred when the infusion rate exceeds 0.11 g/kg/h [50]. For a 70-kg adult, this limit would be approximately 13 hours for 500 mL of 20%, which makes three-in-one admixture infusions safer and easier to administer as a continuous infusion over 24 hours rather than as a separate “IV piggyback” over a brief period, which would require an infusion rate almost twice as fast. In addition, piggyback infusion of lipids is not recommended beyond 12 hours [51].

Recent reports regarding the clinical significance of unstable fat emulsions have emerged. On December 1, 2007, the USP, which is recognized by the Food and Drug Administration (FDA) as the official compendium for drug standards, was the first pharmacopeia worldwide to establish globule size limits for IVLEs [52]. This is notable because IVLEs had been used clinically in the United States for more than 30 years (and Europe for more than 45 years), while most drugs have official USP specifications within 5 years of FDA approval [53]. The USP limits specified two size limits: (i) mean droplet size <0.5 μm and (ii) large-diameter tail, expressed as the percent of fat globules >5 μm (PFAT5 <0.05%). The primary motivation for these limits was to avoid the development of microvascular pulmonary embolism from an excessive population of large-diameter fat globules indicating instability of the emulsion.
Around the time the USP announced its intentions to adopt these limits in 2004 [54], a major lipid emulsion product also changed its conventional packaging from glass to plastic containers. With this change in packaging, the lipid emulsion product now failed the large-diameter globule limits of the USP [55]. Lipid emulsions failing USP limits were also shown to produce less stable emulsions when packaged in syringes for neonates [56], when mixed in TPN admixtures [57], and when used in a multichamber bag premixed for TPN therapy [58]. Moreover, lipid emulsions not meeting pharmacopeial limits were also shown to be associated with significant hypertriglyceridemia in premature neonates when compared to lipid emulsions meeting USP limits [59], although this has not been confirmed in a randomized clinical trial. Finally, in animal studies, lipid emulsions failing USP limits were shown to be hepatotoxic [60]. A recent study intended to explore the extent of physiologic damage from the infusion of unstable lipid emulsions produced evidence of hepatic accumulation of fat associated with oxidative stress, liver injury, and a low-level systemic inflammatory response [61].

Triglyceride clearance is maximal at serum triglyceride levels of up to about 400 mg per dL, and patients who initially have serum triglycerides at this level will tolerate even lesser amounts of fat without adverse consequences. Among patients who have normal serum triglyceride levels at initiation of TPN, serum triglyceride levels are usually not monitored. For those with levels greater than 200 mg per dL it is reasonable to check the triglyceride again after a stable regimen has been attained with lipids below 0.11 g/kg/h. Stable levels below 400 mg per dL are acceptable while receiving lipid emulsions.

For PN therapy, soybean oil emulsions continue to dominate the US market, but recently, an 80:20 olive oil to soybean oil physical has been introduced. A 100% fish oil-in-water emulsion has been available on a compassionate use basis for several years, but is primarily directed at the pediatric population as therapy for PN-related liver disease. However, there are a number of different lipid compositions presently available in Europe and under investigation in the United States [62]. They include various mixtures of soybean oil with medium-chain triglycerides (MCTs), olive oil, and fish oil. In nearly every case, soybean oil is included in sufficient proportions to provide adequate amounts of the essential fatty acids [63,64].

For EN therapy, a number of the lipid types available for parenteral use in Europe are widely available in the United States for enteral administration in complete nutritional diets. Typically, they contain 30% to 40% of the total calories as fat and often contain blends of corn and soy oil. However, in the more specialized enteral formulas, MCTs, fish oil, and even structured lipids are available. Moreover, in some of these
products, the fat content is either severely restricted (i.e., 3% to 10% of total calories for the fat-intolerant patient) or may be as high as 55% for the patient with pulmonary compromise.

Volume

The maintenance of fluid homeostasis is an important goal in critical care. At times, many patients in the ICU become severely volume overloaded as a consequence of parenteral fluid administration and the fluid-retentive state characteristic of critical illness [65–67]. For this reason, when assessing fluid status, it is important to bear in mind the usual contribution of water to body weight or TBW of the patient under normal, unstressed conditions. In normal adults, TBW comprises approximately 50% to 60% of body weight. Because lean body mass is hydrated in a ratio of approximately 4 parts water to 1 part protein, lean tissue is a significant component of TBW. In the clinical setting, acute changes in weight over short intervals primarily reflect net changes in TBW which almost never reflect lean tissue gains in the hospital setting. For example, a 10% increase in weight over 24 to 48 hours represents a proportional increase in TBW and may be associated with adverse clinical consequences, such as greater ventilator dependence, impaired cardiovascular function, and disturbances of electrolyte homeostasis. Even when the patient is considered euvoletic, the contributions to volume from nutritional support are generally limited to approximately 25 mL/kg/d, because other reasons for fluid administration are usually indicated.

Depending on the volume assessments by the primary care team, the amount of nutrition support that may be provided by either PN or EN may be affected. The most significant effect occurs when volume restrictions are imposed. When this happens, hypocaloric nutrition is usually provided owing to the limitations associated with caloric density. Caloric or macronutrient density is the sum total of calories from protein, carbohydrates, and fat, expressed in kilocalories per milliliter (kcal per mL). Generally, the caloric density of typical formulations routinely prescribed for either PN or EN support is approximately 1 kcal per mL, but special forms of each therapy are available that reasonably allow up to 1.5 kcal per mL to be formulated. However, most enteral formulations are commercially available in fixed concentrations and, therefore, are less easily manipulated to the specific needs of the critically ill patient than with the PN admixture. For example, with a 1,000 mL fluid restriction allotted for PN support, the increased macronutrient density could be achieved to attain eucaloric nutrition for adult patients weighing up to 60 kg (25 kcal per kg). Of course, these special dosage forms are generally more expensive than conventional products, and the cost to benefit ratio
has not been fully demonstrated. The usual parenteral formula provided when fluid restriction is necessary is a more standard PN admixture [68], providing 70 g of amino acids and 210 g of glucose (A7D21) approximating 1,000 kcal in a 1 L final volume when compounded from the standard 10% amino acid (700 mL) and 70% dextrose (300 mL) stock solutions, and is usually given for short periods of up to 10 days. Such a formula offers a compromise of the usual desired protein and caloric goals and may provide for a clinical outcome not distinguishable from higher protein, eucaloric regimens [69]. Tables 213.4 and 213.5 provide examples of PN formulations that may be used in the acute critical care setting in adult patients who are fluid restricted (i.e., 1,000 mL for TPN), whose regimens are often hypocaloric for clinical and practical reasons (see Table 213.4), as well as for goal amounts of nutrients in TPN in the absence of fluid restrictions [70]. A recent analysis of highly concentrated TPN admixtures, using a 16% crystalline amino acid solution—containing lipid injectable emulsions in eucaloric amounts, showed them to be stable for up to 30 hours with a net fluid savings of approximately 20% compared with conventional 10% amino acid formulations [71]. Patient-specific PN therapy for pediatric patients (premature, neonate, infant, and adolescent) may be devised using specific practice guidelines [72].

<sup>a</sup> Calories from the eucaloric and euvolemic regimen consists of 1.5 g/kg/d of protein and 25 mL/kg/day, respectively. Eucaloric and euvolemic regimens are in conformance with the ASPEN Guidelines for safe total parenteral nutrition formulations and intended for patients whose present weight is within 10% of ideal body weight.

<sup>b</sup> Assumes a stock bottle of 15% amino acids at 4.1 kcal/g.
Electrolytes

There are seven key electrolytes that must be monitored and provided as necessary in nutritional admixtures. In some cases, certain electrolytes must be given in standard quantities as part of the recommend dietary allowance, whereas others are given in variable amounts and replaced according to the clinical needs of the patient. However, in both cases, the daily requirements can be highly variable especially during acute illness for a variety of reasons, including drug therapy [73, 74]. As well, in all cases, certain electrolytes may be deliberately omitted because of retention disorders associated with certain disease states. This, of course, is more difficult to accomplish with enteral formulas that contain fixed amounts of nutrients and electrolytes. Nevertheless, avoiding the consequences of wide fluctuations in serum electrolyte concentrations that may assume clinical significance in the critical care setting is an important and necessary goal.

Standard Additives

**Calcium.** Approximately 98% of total body calcium is present in the skeleton. Thus, the extracellular concentration in plasma is but a fraction of total calcium stores and is tightly regulated by parathyroid hormone. As absorption of calcium from the GI tract diminishes because of impaired absorption or decreased or absent intake, and serum levels begin to fall, the parathyroid glands sense these changes and secrete parathormone that promotes calcium mobilization from bone to restore normal serum concentrations. However, critical illness disturbs normal calcium homeostasis, and mild depressions of total and free calcium concentrations are common [75]. The parenteral equivalent of the recommended dietary allowance (pRDA) for adults is about 25% of the oral RDA or 200 mg (10 mEq or 5 mmol) of elemental calcium daily. Higher amounts may be used if needed when seeking to maintain calcium at the lower limit of normal, but this does increase the risk of incompatibility with phosphate salts that could produce fatal pulmonary emboli [76–78]. Therefore, if higher amounts are needed, it may be...
necessary to use fat emulsion-free formulas that allow greater amounts of calcium and phosphate to be infused safely. The other alternative, separate infusions of calcium should be done with great care especially if given through peripheral vein, because extravasation injury can be severe [79–81]. In addition, the separate administration of parenteral calcium may be incompatible as a coinfusion with other common infusions applied in the critical care setting, such as sodium bicarbonate. Moreover, if parenteral calcium is given intermittently and the same intravenous line is to be used for other medications, it should be flushed with saline or other suitable parenteral fluid (i.e., D5W) immediately following termination of the calcium infusion. Parenteral forms of calcium are commercially available in three forms, including the gluconate, acetate, and chloride salts. Of these, the gluconate form is preferred in PN admixtures, because it is least capable of forming insoluble products. However, for immediate delivery of calcium in emergency situations such as severe hypocalcemia, the chloride form is the best form for bioavailability reasons, although it is the most reactive salts with respect to compatibility with nutrient formulas and, therefore, should not be employed when compounding TPN formulas.

Magnesium. Another predominant intracellular cation, magnesium, plays a pivotal role in calcium metabolism. For parathyroid hormone to be secreted in response to hypocalcemia, magnesium is required [82]. In certain instances, corrections of serum magnesium concentrations have been sufficient to normalize hypocalcemia [83]. Such responses have been viewed as an indication of the extent of magnesium deficiency [84]. Furthermore, similar to calcium, hypomagnesemia is commonly seen in critical illness, and the goal is similar (i.e., to maintain levels at about the lower limit of normal). The pRDA is about 33% of the oral RDA or 120 mg (10 mEq or 5 mmol) for elemental magnesium per day. The only parenteral form of magnesium available is as the sulfate salt.

Phosphorus. Phosphorus is an essential element involved in numerous life-sustaining metabolic processes. For example, if omitted from a PN admixture, a life-threatening hypophosphatemia may ensue within days of initiating therapy. Like magnesium and calcium, it too is predominantly found in the intracellular compartment. However, because its GI absorption is highly efficient, the pRDA for phosphorus is the same as its oral RDA at 1,000 mg (30 mmol) daily. The use of milliequivalent units to describe phosphorus concentrations in a solution is often mistakenly applied. At this time, the only parenteral form of phosphorus commercially available in the United States is a mixture of
inorganic salts of monobasic ($\text{H}_2\text{PO}_4^-$) and dibasic ($\text{HPO}_4^{2-}$) phosphate ions. Milliequivalents are defined as the molecular weight (in mg) divided by the valence of a single ion, which is determined by the pH of the final solution. Because the pharmaceutic dosage form is a mixture of two ions and has a finite yet variable pH range, the dosage form cannot be accurately described in mEq units. However, because sodium and potassium are the accompanying anions, it has become traditional to order them in terms of mEq units where, for example, 30 mmol of phosphorus is found in about 40 mEq of the commonly available formulations.

Variable Additives

**Sodium.** Sodium is often prescribed in daily amounts ranging from 60 to 100 mEq each day. However, certain clinical conditions preclude the use of sodium beyond minute quantities (i.e., 0 to 20 mEq per day) such as found with florid congestive heart failure, end-stage liver disease, and during attempts to reduce massive volume overload characterized by extensive third-spacing of fluids by volume restriction and active diuresis. In contrast, patients with severe sodium deficits can require daily amounts that may be as much as three to four times higher than typical quantities given to those without sodium restrictions. There is limited to no impact of sodium amounts on nutritional efficacy. Parenteral forms of sodium are available as chloride, acetate, and phosphate salts.

**Potassium.** Potassium is often prescribed in daily amounts ranging from 40 to 80 mEq each day. As described earlier, there are extreme clinical conditions that may require either severe restriction or expansion of the daily dose so that ranges of potassium intake may be from 0 to 400 or more mEq per day. For instance, a severe amphotericin-induced renal loss of potassium of 100 mEq per L with a 4-L urine output can be managed by placing an equivalent amount in the parenteral formula so long as close monitoring of potassium in the serum and urine output is provided. In all cases, serum potassium concentrations should be closely monitored, because the safe clinical range is narrow and levels outside may produce severe and even life-threatening cardiovascular complications. Like sodium, parenteral forms of potassium are available as chloride, acetate, and phosphate salts.

**Chloride.** Chloride salts are widely used for nutrition support. Most often, they are provided as sodium and potassium salts and quantitatively constitute the majority of anions present in nutritional formulations. In the past, an emphasis on chloride salts with parenteral crystalline amino acid formulations had tended to produce an iatrogenic metabolic acidosis. However, these formulations have since been revised and
balanced with an appropriate amount of acetate ions. Thus, it is not necessary to include the inherent concentrations of chloride and acetate present in amino acid products in the additive calculation for the final PN admixture.

**Acetate.** Acetate salts are primarily used when clinically indicated for the treatment of metabolic acidemia. They are the only suitable alkalinizing salt for use in nutritional formulations. With respect to alkalinizing power, acetate is equivalent to bicarbonate, but this requires cellular metabolism to be effective. Bicarbonate salts should never be used in PN admixtures because they can form insoluble carbonates with calcium ions that are present in most nutritional admixtures and, as such, could result in the formation of fatal pulmonary emboli [85].

**Trace Minerals**

To provide a balanced nutritional formulation, trace minerals are generally included in most nutritional formulations. These include chromium, copper, manganese, selenium, and zinc. In addition, iodine, and molybdenum may be present in certain formulations. However, for most acute situations, the absence of trace minerals for brief periods (days to weeks) will not produce clinically significant adverse effects. In contrast, the absence of trace minerals in the patient receiving long-term PN support may lead to significant deficiency [86]. However, because manganese is excreted in bile, there is some concern about manganese overload when chronically provided to patients receiving long-term home TPN. Iron is a special case, because hypoferremia is an invariable consequence of the systemic inflammatory response. Furthermore, large amounts of parenteral iron supplementation may worsen septic states. For this reason, iron is not usually provided in TPN formulas during critical illness and when provided to nonseptic patients in home PN should only be provided when clinically necessary, because iron overload can result in patients with short gut syndromes who have substantial enteral intake. Iron is incompatible in fat emulsion-containing formulas.

**Vitamins**

Multivitamins are an essential component of all nutritional formulations. This is particularly true for PN formulations. During the national vitamin shortage that occurred in the summer of 1988, three patients died as a result of receiving vitamin-free PN in a matter of 3 to 5 weeks [87]. Ultimately, the cause of death was related to acute thiamine deficiency producing a refractory lactic acidosis. As a water-soluble vitamin, thiamine is an important cofactor in the entry of pyruvate into the Krebs cycle as well as facilitating the processing of glucose within the Krebs
cycle. In the absence of thiamine, pyruvate cannot enter the Krebs cycle and is, therefore, converted to lactic acid. The administration of hypertonic dextrose, the major energy component of PN therapy, accelerates the consumption of thiamine and thus accentuates the clinical course of the condition. Therefore, multivitamins are an essential part of any nutrition support regimen.

The FDA has mandated a change in the composition of adult parenteral multivitamins after nearly 30 years of clinical use [88]. The concentrations of four vitamins (thiamine, pyridoxine, ascorbic acid, and folate) were increased by 50% to 100% of previous amounts and, for the first time, vitamin K has been added at 150 mcg per vial. This latter addition may well have some impact on therapeutic doses of warfarin for full anticoagulation as well as for low-dose warfarin therapy for home TPN patients. Lastly, with respect to enteral feeding formulas, the RDA for vitamins is generally met when caloric intakes are between 1,500 to 2,000 kcal per day.

Immunonutrients

There have been a number of nutritional additives that have been alternatively given in supraphysiologic amounts in an effort to improve outcomes. The main ones would include lipids composed of high concentrations of the unsaturated long-chain fatty acids containing n3 or n9 fatty acids, medium-chain saturated fatty acids (MCFAs), and certain “conditionally essential” amino acids. Historically, soybean oil, containing polyunsaturated fatty acids (PUFAs), rich in the 18-carbon essential (cannot be synthesized endogenously) n6 fatty acid linoleic acid and n3 fatty acid α-linolenic acid, has been the main source of fat used in lipid injectable emulsions. These fatty acids are the precursors to the true “necessary” fatty acids, arachidonic and eicosapentaenoic acids from the n6 and n3 families, respectively, whereas the n9 fatty acid, oleic acid is nonessential (i.e., can be synthesized endogenously) [89].

Unfortunately, however, the n6 fatty acids from soybean oil can be proinflammatory and potentially detrimental when provided in large amounts to the critically ill, especially in patients with adult respiratory distress syndrome [30,45–46,90–94]. Therefore, substitution of a portion of the conventional n6 fatty acids with alternative lipid fuels such as the n3 fatty acids (20- and 22-carbon PUFAs) from fish oil, or 18-carbon monounsaturated n9 fatty acids from olive oil, or saturated MCFAs from coconut oil (mostly comprises 8- to 10-carbons), may
modulate the proinflammatory response. Thus, one benefit of these alternative lipid sources is a reduction in the intake of the highly vasoactive n6 PUFAs precursors to ones with less pronounced effects on eicosanoid metabolism by changing the fatty acid composition of cell membranes [64]. The n6 PUFAs produce proinflammatory eicosanoids (i.e., prostaglandins, prostacyclins, thromboxanes, leukotrienes) and increase the responsiveness of cytokines (i.e., interleukin [IL]-1, IL-6, and tumor necrosis factor) which subsequently lead to an increased systemic inflammatory response. Meanwhile, the n3 and n9 lipids lead to eicosanoids that are less proinflammatory and even anti-inflammatory. Another benefit is related to a unique metabolic action of the substituted lipid(s) that may have favorable clinical implications. In the case of MCFAs, their metabolism is independent of carnitine transport into the mitochondria with rapid oxidation and less interference with the reticuloendothelial system, whereas olive oil may be better tolerated with respect to liver function in certain patients receiving conventional soybean oil–based formulations [95].

Of the amino acids used in clinical nutrition, arginine and glutamine have purportedly been shown to exert favorable immune effects in patients receiving nutrition support. Arginine has been shown to stimulate T-cell function and wound healing, but may be harmful in certain patients under certain conditions depending on dose [96,97]. Thus, its role in immune enhancement has not been clearly defined, and it is most often given as part of a complex nutritional formula containing other potential immunonutrients. Nonetheless, there appears to be a correlation of demonstrable benefits at doses exceeding 4% of the total energy intake [97]. Glutamine is the most abundant amino acid in the human body, a precursor to glutathione, and an important nutrient for rapidly dividing immune cells such as lymphocytes and macrophages. Despite its abundance, serum and tissue glutamine concentrations fall during critical illness, which largely reflects its diverse needs during acute metabolic stress. Its role in clinical nutrition is also not well defined, and, in a large clinical trial in ICU patients, no differences in outcomes were noted between groups receiving 20 g per L versus a conventional enteral formula that was isonitrogenous and isocaloric [98]. Data with parenteral glutamine tend to be more positive in the critically ill, which may reflect the prominent first-pass clearance of enteral glutamine limiting systemic appearance of the amino acid.

Two recent clinical trials have greatly altered the conventional viewpoint that immunonutrients have a net beneficial effect, that is, the so-called “REDOXS” [99] and “METAPLUS” [100] trials. In a recent commentary that included the lead authors of these studies, they point out the “signal of benefit” that has been widely acknowledged comes from older studies from single-center trials, whereas evidence of a “signal of
harm”, as they have recently reported, is much stronger because the data comes from two large, adequately powered, multicenter trials [101]. They, and others [102,103], have concluded that these diets should not be routinely administered to critically ill patients.
DIFFERENCES BETWEEN ENTERAL AND PARENTERAL NUTRITIONS

Nutrition support may be provided in a variety of ways ranging from noninvasive approaches such as dietary counseling for food and oral supplements to invasive forms of therapy. Of the interventional approaches to nutrition support, these can be accomplished by aseptic placement of intravascular catheters (i.e., PN), or by extravascular devices placed into the GI tract (i.e., EN). Each invasive form of nutrition support has its advantages and disadvantages, and the selection of either approach must be individualized.

Routes of Administration

Enteral Nutrition Options

Like PN therapy, EN can be delivered in a variety of ways with some potential advantages of one access route over the other. The options include gastric, duodenal, and jejunal placement of various enteral feeding catheters. The simplest technique is the nasogastric placement of a feeding tube into the stomach. However, this approach is often associated with the greatest degree of GI intolerance and thus reduced delivery of protein and energy compared to feeding tubes placed in the intestine. A higher degree of successful feeding is likely with nasoenteric tubes or those placed via fluoroscopic, endoscopic, or surgical placement of the feeding catheter beyond the ligament of Treitz. Furthermore, enteral feeding catheters placed in the upper jejunum may allow feeding of patients with severe pancreatitis [104]. However, placement of feeding tubes in the jejunum postinjury rarely occurs spontaneously and generally requires fluoroscopic or endoscopic assistance, which is expensive and can delay feeding. A recent study of mechanically ventilated patients who were fed via a nasogastric or nasojejunal feeding tube for 10 days showed no differences of energy delivery, 71% versus 72% of target, nor rates of ventilator-associated pneumonia, 20% versus 21% [105]. Of note, there was higher incidence of “minor” episodes of GI bleeding in the nasojejunal-fed group, but of the two promotility agents used in this study (metoclopramide and erythromycin), they received erythromycin more frequently than in the nasogastric-fed group (87% vs. 62%, \( p = 0.001 \)). Erythromycin is known to cause epigastric distress which may be responsible for the GI bleeding observed. Finally, a recent
Cochrane meta-analysis of the differences between postpyloric versus gastric tube feeding for preventing pneumonia and improving nutritional outcomes in ICU patients found “moderate-quality” evidence of a 30% reduction in the rate of pneumonia associated with postpyloric feeding, as well as “low-quality” evidence showing an increase in the amount of nutrition delivered [106]. The use of a postpyloric feeding tube was recommended, when feasible.

Parenteral Nutrition Options

PN may be provided by either peripheral or central venous access. Peripheral venous access is clearly less invasive and has minimal complications. The most significant complications are related to maintenance of the patency of the venous catheter and thrombophlebitis and the limited use of each venipuncture site for a relatively short duration. Most peripheral vein catheters will last between 48 and 72 hours from the time of the initial insertion, and, therefore, a systematic rotation of other infusion sites must be performed. Ultimately, however, the number of viable peripheral venipuncture sites is limited and generally of little practical value in the ICU setting. Moreover, owing to the osmolarity limits of these low-flow blood vessels, very large fluid volumes are required to approach protein and energy requirements for most patients, which is not practical in the ICU setting. Peripherally inserted central (venous) catheters (PICCs) generally last longer and can even be used to provide hypertonic PN admixtures. However, the inability to change catheters over guidewires for PICCs, and a greater likelihood of mechanical complications, makes this a less desirable alternative to a central venous catheter.

By far, central venous catheterization is most commonly used to deliver PN therapy. Invariably, central venous access is necessary for virtually all patients requiring ICU care, so the delivery of PN therapy does not introduce unique clinical risks associated with catheter placement (i.e., pneumothorax, catheter malposition, catheter infections, and so forth). In addition to supplying nutrition support, the PN admixture can also be used as a vehicle to provide intensive metabolic support such as replacement of large amounts of electrolytes and correction of acid–base balance, which otherwise could not be accomplished by peripheral vein or EN therapy, largely because of osmolarity limitations. Moreover, it has also been used as a vehicle for selected pharmacotherapies [107].
Approximately 25 years ago, there was a significant push toward the use of EN over PN as being a safer mode of nutrient supplementation. The principal benefit purportedly associated with the use of EN is reduced infectious complications compared with PN support in the critically ill. Three key investigations conducted in trauma patients were largely responsible for promoting EN over PN, showing that patients receiving the latter mode of nutritional support had significantly higher rates of infectious complications [108–110]. In addition, this association appeared to be subsequently confirmed by meta-analysis [111]. However, as eloquently pointed out by Jeejeebhoy [112] in 2001, studies such as these are significantly flawed in that the groups receiving PN have significantly higher energy intakes that are associated with significantly higher blood glucose levels, which predispose them to nosocomial infections. Higher energy intakes are easily obtainable via PN, whereas they are more difficult to achieve with EN during acute illness as a result of GI intolerance [113].

Subsequently, Simpson and Doig [114] conducted a more sensitive approach to meta-analysis comparing studies of PN versus EN only in the critically ill. Previous systematic reviews of the risks and benefits of nutrition support have relied on a composite scales technique that combines certain dimensions of the quality of the selected trial used in the meta-analysis into a combined summary score. Consequently, important differences in methodologic quality (i.e., concealment of allocation, appropriate blinding, and analysis according to the intention-to-treat principle) may be overlooked, making well-conducted studies appear poorly conducted [115]. In contrast, the approach by Simpson and Doig in assessing PN versus EN, using the intent-to-treat principle, applied a component scale technique and demonstrated increased infectious complications with PN, but more importantly, reduced mortality by 56% compared with enteral feeding. This impressive benefit was also shown to be largely the effect of early feeding, because a post hoc analysis of TPN versus early enteral feeding showed no difference in mortality [114]. The latter finding was in contradistinction to previous analyses applying the composite scales approach in assessing the benefits and risks of PN [111,116]. Subsequently, in a large multicenter, randomized clinical trial (1,372 patients), Doig et al. have shown that the use of early PN (ready-to-mix, three-chamber bag containing standard amounts amino acids, glucose, lipids, and electrolytes, but at different infusion rates for energy targets of up to 35 kcal/kg/d) versus “standard care” (which was defined pragmatically outside the PN protocol) did not result in significant differences in 60-day mortality or infection rates, and, thus, there was no associated harm from early PN therapy [117].
The seminal publication by Van den Berghe et al. [118] in 2001 showed a significant morbidity and mortality benefit for surgical ICU patients receiving adequate nutrition either enterally or parenterally or by combination when blood glucose levels were aggressively managed with the intravenous infusion of insulin, and the clinical significance of hyperglycemia in nutritional support was clearly established. Two groups of patients were studied ($n = 1,548$) to receive either “intensive” or “conventional” insulin therapy concurrent with PN. Blood glucose management assigned to the “intensive” insulin therapy group was treated with an insulin infusion if levels were above 110 mg%, whereas, in the “conventional” insulin therapy group, insulin was initiated at levels above 215 mg%. The standard infusion consisted of 50 units of insulin in 50 mL of 0.9% sodium chloride solution (1 units per mL), and the maximum insulin dose was arbitrarily set at 50 units per hour for all groups. Hypoglycemia was defined as a blood glucose determination of 40 mg% or less. Within 24 hours, on average, all patients received approximately 1 g of protein and 19 kcal/kg/24 hours, respectively. Significant reductions in in-hospital morbidity (e.g., renal and hepatic function, bloodstream infections, polyneuropathy) and mortality were observed in the “intensive” versus “conventional” insulin therapy group, where, for example, control of the morning blood glucose levels for all patients was significantly different between groups ($103 \pm 33$ mg% vs. $153 \pm 19$ mg%, respectively). Additional significant clinical benefits (e.g., days on ventilator, lower Simplified Therapeutic Intervention Scoring System-28 scores) were also noted for those patients with ICU stays exceeding 5 days.

A follow-up study by Van den Berghe et al. [119] in 2006 was conducted, but this time it was performed in medical ICU patients receiving EN. Unfortunately, the nutrition support data were not as clearly presented as in the 2001 study, but inferences are made as to how it was supplied. The nutritional goals stated from the outset was 22 to 30 kcal/kg/24 h (with approximately 20% to 40% of energy as fat calories) and protein at between 0.5 and 1.5 g/kg/24 h, with EN beginning as early as possible, once the patient was hemodynamically stable. Subsequently, in the results, two figures are shown that give more details about the success of achieving the stated nutritional goals during this study. One depicts the “total intake of nonprotein calories (kcal per 24 hours)” versus “day” showing that a steady amount of calories (between approximately 1,500 and 1,600 calories per day) were achieved by days 3 and 4 of the 14-day profile. The other depicts the “fraction of kilocalories administered by
enteral route” versus “day” showing achievement of 50% of total calories via EN at day 7 and roughly 70% by day 12 of the 14-day profile. The slow progression of EN support is expected in critically ill patients, as contrasted from their previous PN study showing rapid advancement of protein and calories [118]. No significant improvements of mortality were noted, but morbidity (e.g., acute renal failure, days on ventilator) was reduced for patients receiving “intensive” insulin therapy. Of note, for the patients staying in the ICU for less than 3 days (n = 433) (“and for whom data were censored after randomization”) [119], 56 deaths occurred in the “intensive” versus 42 deaths in the “conventional” insulin infusion group. Moreover, although the severity of hypoglycemia was similar between groups, hypoglycemia was more common in the “intensive” insulin treatment group. A subsequent logistic regression analysis revealed hypoglycemia to be an independent risk factor for death, prompting the investigators to speculate “that the benefit from intensive insulin therapy requires time to be realized” [119]. For patients staying 3 days or more, the mortality benefits seen in the previous study [118] were similarly observed and may support their theory of a time-dependent benefit of aggressive blood glucose management. From a nutritional perspective, the slow progression of protein and calories via the enteral route suggests significant caution in applying aggressive insulin therapy in medical ICU patients receiving EN support only, because parenteral glucose may make hypoglycemia less likely.

A closer evaluation of the manuscript and the table provided in a supplemental appendix reveals that rather marginal amounts of protein and adequate calories were given to the “intention-to-treat group (n = 1,200)” at approximately 40 g of protein and 1,200 kcal daily, whereas in the “long stayers (in ICU 3 days or more),” approximately 50 g of protein and 1,500 kcal daily were given. It is also obvious from this table that the parenteral infusions were glucose only and not TPN, and that the protein intake in the first 72 hours was about 10 g protein per day. Thus, these critically ill patients did not receive early, adequate feeding, which should be the goal in the critically ill. Furthermore, this less than optimal nutritional therapy was provided at a rather high cost in terms of hypoglycemia with an incidence of 25.1% versus 3.9% in the intensive versus conventional treatment in the long stayers in the ICU. More recently, the risk of significant hypoglycemia in patients receiving EN versus PN has been observed in the so-called “CALORIES” trial. In a randomized trial comparing the route of administration in early nutrition support in critically ill adults, there were no differences between groups in 30-day mortality; however, the EN group experienced significantly higher rates of vomiting and hypoglycemia [120]. GI intolerance would be expected to be higher via EN, but of note, caloric intake was similar in the two groups even though the target delivery of 25 kcal/kg/d was not
achieved in a majority of the patients in each study group. Nonetheless, as pointed out by the investigators, the focus of the evaluation of the delivery route was uncomplicated by the dose of nutrients. Importantly, despite the same amounts of calorie intake over 5 days, hypoglycemic episodes occurred in 74 of 1,197 patients in the EN groups versus 44 of 1,191 in the PN group ($p = 0.006$). Whether this effect was the result of less “absorbable” calories as a result of vomiting and/or the difficulty in managing EN patients with more precise doses of insulin, was not addressed in this study.

A series of recent randomized clinical trials have further clarified the role of nutritional support in the broader group of critically ill patients in general ICUs. A recent large pragmatic trial by Harvey et al. [120] of TPN compared to EN where both groups received 15 to 20 kcal per kg with a goal of 25 kcal per kg, that is, were effectively permissively underfed, demonstrated no morbidity or mortality differences. This study along with the Heidegger et al.’s trial [121], where supplemental TPN at 103% of energy versus 77% of energy (goal 25 kcal per kg for women and 30 kcal per kg for men) with better protein intake (0.8 vs. 1.2 g per kg) in the former, reduced infection rates, strongly support the contention that in modern clinical practice where feeding is with more modest goal intakes of <30 kcal per kg approximating energy expenditure or at lower levels of permissive underfeeding in conjunction with control of blood glucose to <180 mg per dL have made TPN as safe as EN. Permissive underfeeding which is providing a fraction of between 50% and 75% of the caloric expenditure, usually estimated in most studies to be approximately 25 kcal per kg for the majority of critically ill patients in the ICU, certainly makes blood glucose control easier. Whether it improves morbidity or mortality compared to full feeding at 25 kcal per kg is uncertain when the control group receives about 100% of this estimate rather than some larger multiple as was common in earlier studies, and when blood glucose is well controlled. One trial that did compare supplemental TPN feeding in the first week of critical illness that provided 25 kcal per kg in the control group versus <10 kcal per kg in the first week and 15 to 20 kcal per kg over the entire study period had increased infections and ventilator and renal replacement requirements, suggesting a disadvantage to early TPN compared to inadequate feeding [122]. However, the unusual use of hypertonic dextrose, which can be immunosuppressive, for 48 hours before initiation of TPN make this a difficult study to evaluate particularly in light of the more recent evidence of the relative safety of TPN. In a trial of early TPN with a goal of approximately 35 kcal per kg in critically ill patients with short-term relative contraindications to early EN, the treatment group received about 18 kcal per kg in the first week and the control group 8 kcal per kg with protein intakes of about 50 g per day and 25 g per day, respectively.
There was a modest improvement in ventilator days and less muscle wasting in the better fed group. In the two trials [123,124] of planned permissive underfeeding conducted by Arabi’s group, both the treatment and the permissive underfeeding groups were underfed (59% vs. 71.4% and 46% vs. 71%, respectively) with equal protein intakes in both groups and in both studies by design. The earlier Arabi’s study [123] found an improved hospital mortality as a post hoc finding which was not confirmed in the larger trial [124] (i.e., the so-called “PERMIT” trial) with a greater difference in caloric intakes and a longer duration of feeding in this later study despite similar control intakes in both studies. The only disadvantage with the higher calorie intake for the more recent study is that this led to a greater volume intake with a more positive fluid balance and the need for more renal replacement therapy. Thus, whether permissive underfeeding improves outcome over full feeding at 25 kcal per kg has not been definitively determined, but smaller volumes are required with permissive underfeeding. This may be an important factor when the underlying clinical problem is acute respiratory failure. In another recent trial [125] of acute lung injury, adverse mortality experience was found in the intensively fed group receiving nearly adequate energy (84.7% vs. 55.4%) where presumably greater volume was provided. This trial was stopped early because of the higher mortality occurring principally in the first week of therapy in the group with higher energy intake where a positive fluid balance might be particularly harmful. Two other trials [126,127] in acute respiratory failure failed to show an outcome difference between trophic feeding enterally of <5 kcal per kg versus approximately 15 kcal per kg for the first week, but no protein supplementation was provided in the better fed group. Thus, permissive underfeeding was not beneficial in this instance compared to grossly inadequate feeding. In conclusion, recent work has not only better defined the energy goal optimal for the general ICU patient as probably between 50% and 100% of 25 kcal per kg while holding protein constant but has also reinforced the point that a goal is different from what is actually provided, and it is the latter that is of cardinal importance. Although it is possible to achieve these modest goals by feeding enterally or by supplemental feeding parenterally, in practice, underfeeding in relation to goals is the usual outcome for both PN and EN of the critically ill. In such circumstances, permissive underfeeding if protein intakes are maintained at 0.8 to 1 g per kg or even higher should lead to outcomes as good as full feeding at 25 kcal per kg and, probably, better than those found with caloric intakes substantially greater than 25 kcal per kg as was the previous norm. Given the difficulties of assessing caloric needs in the heterogeneous clinical states found in the critically ill without direct measurement of energy expenditure, permissive underfeeding using simple estimates of caloric expenditure like 25 kcal per kg or those
derived by use of various other predictive formulas also limits the likelihood of overfeeding in some patients.

In conclusion, much of the increase in morbidity related to PN and EN is as a result of hyperglycemia, which can be significantly reduced by intensive insulin therapy. The level of glycemia necessary to accomplish this goal, whether <110 mg per dL or only <150 mg per dL, is not yet defined. Surgical patients being adequately fed may benefit from the lower range, but a recent large study of intensive insulin therapy alone without full feeding in mixed populations of medical and surgical patients have significantly lower mortality with looser control of <180 mg per dL versus tighter control (81 to 108 mg per dL) [128]. A possible interpretation is that to accomplish early, adequate feeding requires some parenteral feeding in many critically ill patients who may also serve to minimize the risks of hypoglycemia when employing tighter glucose control.

Tolerance

Enteral Nutrition

Tolerance to nutrition support interventions is highly variable and principally depends on the clinical condition of the patient and the mode of administration. In general, critically ill patients are least able to tolerate all forms of nutritional support. This is particularly true with EN and often limits the amount of protein and calories that can be provided, because GI intolerance to feeding is common. As well, a number of other factors associated with ICU care can also interfere with its efficacious delivery [129]. The use of specialized formulations that provide elemental forms of the macronutrients, or are of reduced osmolarity, or of low fat content, may reduce the degree of GI intolerance. Moreover, the use of prokinetic agents, such as metoclopramide and erythromycin, may benefit some patients as well, whether used alone or in combination, but tachyphylaxis limits its use beyond 5 to 7 days [130]. Nevertheless, despite these preventive measures, GI intolerance cannot be successfully managed for all patients. A recent Cochrane meta-analysis assessed the efficacy of metoclopramide for the postpyloric placement of nasoenteric tubes [131]. Although admittedly, the four trials identified for the analysis provided very–low-quality evidence, the authors reported that at doses of 10 and 20 mg, they were equally ineffective when compared to placebo or
no intervention. Despite this, they reported it is unlikely that a randomized clinical trial would be performed given the lack of efficacy in this review, and because the available trials for this analysis were all performed before 1995.

Other maneuvers, such as diluting the enteral feeding formula, rarely alleviate the problem and generally should not be undertaken. Providing monomeric or oligomeric formulations with reduced fat content at full strength, given at low rates (i.e., 20 mL per hour) and slowly advanced (i.e., 10 mL per hour every 6 to 12 hours as tolerated) can be applied, but likely of little benefit as well. Three relevant clinical studies in the ICU have focused on additional methods of EN delivery: (1) very low feeding rates or “trophic feeding”; (2) increasing caloric density; and (3) volume-based EN delivery. In the “trophic feeding” study, patients who were expected to require mechanical ventilation for at least 72 hours were randomized to receive “full-energy” EN (25 mL per hour and increased by 25 mL per hour until full feeding is accomplished, 25 to 30 kcal/kg/d) or “initial trophic” EN (10 mL per hour) for 6 days [126]. There were no differences in clinical outcomes, and, as expected, fewer episodes of GI intolerance were observed in the patients receiving the “trophic” regimen.

Increasing the caloric density has also been shown to be possible without increasing adverse effects in the ICU. In a recent multicenter study of mechanically ventilated patients, a standard 1 kcal per mL enteral formula was tested against a concentrated one at 1.5 kcal per mL (maximum rate: 100 mL per hour) for up to 10 days [132]. Daily caloric intakes were estimated to average 1,832 versus 1,125 kcal per day for 1.5-versus 1.0-kcal per day diets, respectively (~EN dose range: 25 to 35 kcal/kg/d, based on IBW). The main difference in the nutritional composition was from the additional calories from fat and carbohydrate in the commercial enteral products used in this study. The two groups received similar volumes of EN (1,221 vs. 1,225 mL per day), but obviously nearly 50% more calories. Of note, the concentrated EN formula was not associated with an increase of GI intolerance (higher gastric residual volumes, diarrhea).

Typical delivery of EN is based on a fixed hourly rate-based feeding (RBF) method, and, according to a recent report, it is shown why EN therapy in the critically ill leads to underfeeding (~50% of caloric requirements) is largely because of delays in initiation, underordering by the physicians, and reduced delivery through frequent interruptions or periods of cessation [133]. Consequently, the patient receives less volume and fewer calories. By adjusting the EN infusion rate upwards to make up for the “interruptions” in delivery, that is, a “volume-based feeding” (VBF) protocol ensures that the intended 24-hour supply of nutrients is achieved. In a small study to evaluate the efficacy of this feeding method, McClave and colleagues found that VBF: (1) allowed more calories than
RBF (78% vs. 62%, respectively, of goal: 25 to 30 kcal/kg/d); (2) significantly lowered cumulative caloric deficits during the study, up to 7 days (−776 kcal vs. −1,934 kcal, respectively); and (3) was no better than RBF with regard to incidence of “uninterrupted” EN periods during the study (52% vs. 55%, respectively). A summary of the important clinical issues affecting the delivery of EN therapy appears in Table 213.6.

EN, enteral nutrition; GI, gastrointestinal; PN, parenteral nutrition.

As a general rule, patients who suffer multiple trauma excluding head injury are usually more tolerant of enteral feeding and allow quicker advancement than those critically ill patients who have closed head injury, sepsis, or are postoperative. Consequently, the time course to achieve eucaloric nutrition is usually longer than with PN.

### Parenteral Nutrition
In contrast, patients receiving PN will physically tolerate large amounts of nutrients when given by intravenous administration. The “physiologic brake” that obviously limits EN is not readily apparent. Metabolic abnormalities, such as hyperglycemia and electrolyte and acid–base disturbances, can be easily ascribed to the consequences of the metabolic response to injury, rather than recognizing the contribution of overly aggressive PN support. Furthermore, these iatrogenic metabolic abnormalities are often addressed independently from the PN admixture, such as by separate infusions of insulin, fluid, electrolytes, and so forth, without modifying the PN regimen. The net effect of parenteral overfeeding can unnecessarily complicate the critical care of such patients and lead to significant increases in morbidity and even mortality. However, once metabolic homeostasis is achieved, the time course to reach eucaloric nutrition support is usually brief compared with EN therapy.

Fixed Versus Variable Amounts of Nutrients

Enteral Nutrition

There is limited opportunity to manipulate the contents of EN formulations because these products are premade as “complete” commercial products. Of course, they may be modified by the addition of various nutrient modules, but cannot easily be specifically tailored to the patient, especially during acute illness. For example, a number of electrolyte additives may precipitate the complex feeding formulas and cause clogging of the feeding tube. The addition of other components to the enteral formulation increases the osmolarity, which is an important consideration for enteral feeding, as well as increasing the risk of incompatibilities [70]. Thus, the flexibility of enteral therapy is limited, which may make it difficult to achieve the proper balance of nutrients during severe metabolic stress. Once the stress response remits and major organ function improves, this becomes a less pressing concern.

Parenteral Nutrition

Major stability issues associated with PN admixtures preclude the manufacture of ready-to-use commercial products. Of these, the interaction between certain amino acids with dextrose forming oxidized end products, known as the Maillard reaction, is generally acknowledged
The use of multicompartiment bags offer a possible alternative to these reactions, but as with enteral products, they too become clinically limiting in the unstable patient in the acute care setting. Thus, PN admixtures are most often made extemporaneously from individual commercial ingredients (i.e., amino acids, dextrose, lipids, electrolytes, and so forth) by qualified pharmacy personnel. The introduction of automated compounding devices and their subsequent widespread use has made the practice of patient-specific admixtures a relatively easy task. Thus, even the sickest of ICU patients can receive some form of nutrition support by the prescribing of unique and specifically designed formulations to support the protein synthetic response to injury.

Costs

Enteral Nutrition

Historically, EN formulations have been a fraction of the cost of PN admixtures because they are ready-to-use and largely comprised of polymeric forms of macronutrients. However, with refinements in these products to construct oligomeric or monomeric forms of protein and carbohydrates, the so-called elemental formulas, the costs have increased substantially. Moreover, the addition of novel nutrients, such as ω-3 fatty acids, glutamine, arginine, and others to produce nutritional supplements that may have pharmacologic effects, particularly with respect to immune function, has increased costs that now exceed most PN formulations per kilocalories. Although the data are promising for these innovative formulations in terms of their potential to reduce length of stay and, possibly, infectious complications, the full extent of these claims have not been fully substantiated.

Parenteral Nutrition

By historical comparison, PN was always more expensive than EN therapy. There were many good reasons for this, considering the product had to be specially compounded under aseptic conditions to be suitable and safe for intravenous administration. Because the methods of commercial production improved and became more efficient and competition increased, the costs of PN therapy have significantly declined. Compared with specialized formulas that contain immunonutrients or certain concentrated enteral products, the present costs of PN therapy are equal or, in many cases, less expensive. In contrast, for conventional, polymeric EN supplements, the cost of the formulations is still substantially less than PN formula costs. However, the placement of an enteral feeding tube and components (pumps, sets,
and so forth) is dedicated to the provision of nutrition support, whereas central venous lines are already being used for the provision of intravenous fluids, medications, and blood tests. Therefore, additional costs of even conventional EN therapy must be considered.

**Complications**

The complications or adverse patient events associated with PN and EN include mechanical, septic, and metabolic misadventures [136]. For example, mechanical complications of invasive nutrition support are often associated with the misplacement of various types of feeding access devices (i.e., vascular injury or pneumothorax). With experienced clinicians, the incidence of such complications is substantially reduced and clinically acceptable at about 1% to 2%.

Metabolic and associated septic complications are more common and can have a significant impact on patient outcomes. Severe disturbances in fluid, electrolyte, and acid–base homeostasis are commonly associated with high rates of morbidity and mortality in the ICU. This is especially true for patients with significant heart disease [137]. As well, septic complications in association with hyperglycemia and infections in critically ill patients receiving PN or EN are at least equally significant, if not even more so [138]. Therefore, a more modest provision of energy intake (i.e., approximately 25 total kcal/kg/d) should be the overall goal of therapy by whatever route of delivery and is most likely to succeed, and, with this, fewer nutrition-related complications are likely. However, in the first 3 to 7 days of EN and PN, providing at least 50% of the estimated energy requirement along with protein intake of at least 1 g per kg may be a reasonable compromise meeting the definition or early, adequate feeding while lowering the risk of metabolic and infectious complications. Of note, in the recent permissive underfeeding trial, Arabi et al. showed no differences of clinical outcomes (90-day mortality, feeding intolerance, infections, or hospital length of stay) between groups fed EN for up to 14 days [124]. Not surprisingly, significant increases were observed in the “standard feeding” group versus those in the “permissive underfeeding” group in terms of (1) insulin dose and requirements ($p = 0.02$); (2) blood glucose concentrations ($p = 0.04$); (3) fluid balance ($p = 0.001$); and (4) renal replacement therapy ($p = 0.04$). Also, protein intakes were similar between groups, but daily intake was <1 g/kg/d. Of course, permissive underfeeding should not be applied to high-risk patients, and indirect calorimetry can be helpful for patients
with preexisting moderate-to-severe malnutrition.

**Appropriate Application of Nutritional Support**

Nutritional support does not improve outcomes for operative patients who are well nourished, no matter what route of administration it is given. A number of examples appear in the medical literature supporting this contention. For example, a randomized clinical trial of perioperative nutrition support only found significant improvement in the malnourished group irrespective of feeding mode [139]. Heslin et al. [140] reported no benefit with enteral tube feeding for patients with GI cancer without significant weight loss. In fact, the routine provision of EN in well-nourished patients may cause significant impairments in ventilatory function and mobility [141]. Finally, an extensive review of the literature has corroborated the lack of benefits in the standard prescription of nutrition support for patients who initially are well nourished and undergoing moderate stress following major thoracoabdominal surgery [142]. There is reasonable support for early and adequate feeding for the most critically stressed even when initially well nourished such as those with closed head injury, severe multiple trauma, major third-degree burns, and severe sepsis, not to prevent the development of malnutrition but presumably to limit the severity of the systemic inflammatory response.

In contrast, invasive feeding of the malnourished patient is likely to be effective in a variety of clinical scenarios. This is particularly true during acute metabolic stress, where ongoing catabolism results in significant daily losses of body protein. Patients with weight loss classified as moderate (i.e., 10% or more) or severe (i.e., 20% or more) from usual or IBW are most susceptible to nutrition-related complications, such as infection or wound dehiscence. The absence of nutritional intervention in this vulnerable population for protracted periods of time (i.e., greater than 7 to 10 days) may have a significant impact on outcome. Moreover, even the initially well-nourished patient cannot sustain the protein synthetic response to injury for long periods. For example, in a randomized study of the effects on outcome of postoperative feeding with TPN, those who were inadequately fed for 14 days had a significantly higher morbidity and mortality [143]. Patients who suffer multiple traumas, major burns, or closed head injury are a unique group. Although generally well nourished at the outset, the severity of catabolic response and the likely duration of substantially longer than 7 days make early nutritional intervention within the first few days beneficial.
MONITORING PARAMETERS FOR NUTRITIONAL SUPPORT

Electrolytes

During critical illness, severe electrolyte disorders are common and are primarily the result of various concomitant etiologies, including changes in (a) the function of major organ systems, especially the kidneys; (b) fluid balance affecting intravascular volume and the hormonal milieu produced as a result of the metabolic response to severe stress(es); (c) intracellular or extracellular shifts of ions associated with acid–base disturbances; and (d) multiple drug therapies. Renal dysfunction has profound effects on electrolyte balance by influencing the absorption and excretion of, most notably, sodium, potassium, magnesium, phosphorus, and titratable acids. As renal function declines, the excretion of these electrolytes decreases, and, therefore, the PN admixture must be adjusted accordingly. For example, in some cases, electrolytes are significantly reduced, whereas, in other circumstances, they are entirely omitted from the daily admixture. As well, chloride ions are often substituted with alkalinizing anions such as acetate to combat the metabolic acidosis associated with renal failure.

Fluid overload is a common finding among critically ill patients related to intraoperative support of renal blood flow and function, acute volume resuscitation with crystalloids in the ICU, and the administration of multiple intravenous medications that may produce its own set of complications. For example, acute increases of 10% or greater above usual body weight over short intervals clearly reflect a significant expansion of TBW that may impede the weaning of the patient from mechanical ventilation. Thus, clinical efforts to return to the patient’s premorbid weight, such as by aggressive diuretic therapy and concentrating intravenous medications in the least diluent volume possible, are often used. More recently, the use of hemofiltration procedures to accomplish this goal has proven quite effective. Despite “third-spacing” of fluids, the consequences of the antidiuretic and antinatriuretic responses of stress often present as a hyponatremia and can be mistakenly treated by the parenteral administration of sodium salts in an effort to correct the serum sodium concentration. However, given that sodium essentially distributes in TBW, one can easily calculate that, in fact, the patient is both fluid and total body sodium overloaded. Hence, clinical maneuvers to address the problem should be directed at increasing both sodium and free water losses, with gradual restoration of
serum sodium concentrations. A clinical example of this estimation appears in Table 213.7.

</tr>
</tbody>
</table>

**Excess total body sodium**

\[
\text{Excess total body sodium} = 8,190 - 5,880 = 2,310 \text{ mEq}
\]

Assumptions: premorbid weight = 70 kg male; presently = 91 kg; serum sodium = 140 mEq/L (normal); presently = 130 mEq/L; total body water = 60% (for males).

The acute intracellular or extracellular shifting of electrolytes is primarily the result of the effects of changes in acid–base homeostasis and serum insulin concentrations. In the former case, serum potassium concentrations are most affected by changes in acid–base status. Potassium is predominantly an intracellular ion whose concentration in the intracellular compartment is much higher than its extracellular concentration. When arterial pH falls below normal, potassium shifts to the extracellular compartment and hyperkalemia occurs, and, conversely, metabolic alkalosis produces hypokalemia.

Insulin has also a profound effect on the shifting of potassium, magnesium, and phosphorus between the intracellular and extracellular environments. In fact, the life-threatening refeeding syndrome that occurs in severely malnourished patients is associated with the shifting of these electrolytes from the extracellular to the intracellular compartments [144]. In the atrophic heart muscle characteristic of severe malnutrition (i.e., greater than 30% below IBW), severe reductions of serum potassium (i.e., less than 3 mEq per L) and serum phosphorus (i.e., less than 0.2 mg per L) related to feeding may have life-threatening
electrophysiologic consequences [145].

Finally, critically ill patients commonly receive multiple drug therapies intravenously for a variety of clinical reasons and include, for example, cardiovascular agents, vasopressors, diuretics, anesthesia/sedation therapy, crystalloids, colloids, antibiotics, anticoagulants, and so forth. These can cause clinically significant effects by altering intended drug actions (i.e., toxic synergism, reduced drug effects) or by addition of substantial diluent volumes (i.e., greater than 500 mL), worsening a fluid-overloaded state. The clinical care of acutely ill patients with severe fluid and electrolyte disorders can be optimally managed through intensive metabolic monitoring and selective manipulations of PN admixture components [73,74,145].

**Insulin and Glucose Homeostasis**

Notwithstanding its regulatory role in glucose homeostasis in terms of glucose production and breakdown in the liver, as well as its facilitated transport of glucose into muscle and other obligatory tissues, insulin is a complex hormone that exhibits numerous metabolic effects that may be of significant clinical consequences for the critically ill. The mechanisms by which abnormally elevated blood glucose concentrations of critically ill patients produce metabolic dysfunction have been described [146]. With respect to infectious risk, the ability of mononuclear (macrophages and monocytes) and polymorphonuclear neutrophils to exert phagocytic, oxidative bursts, and killing functions is significantly impaired. Thus, infections of the bloodstream, lungs, and superficial wounds (i.e., any surgical incision site, intravascular and extravascular catheter sites, or other topical sites of injury) are significantly increased following periods of hyperglycemia.

Glucose homeostasis is best achieved when parenteral insulin is given in an effective manner. A review of the methods of administration employed emphasize that the route of insulin delivery should be commensurate with the means of administration of carbohydrate calories [147]. In the acute phases of critical illness, patients receiving PN should receive intensive insulin therapy [118]. Once, stabilized (i.e., patients receiving the largest source of glucose as parenteral calories), insulin should be given in the TPN admixture in amounts sufficient to cover the caloric intake from this source over 24 hours. When exclusive PN therapy is given, 24-hour glucose intake may account for as much as 150 to 300 g per L daily (510 to 1,020 kcal), requiring substantial amounts of insulin in the admixture, and can be effectively accomplished [147]. As well, in some cases, supplemental “low-volume, full-strength” EN may provide 50 to 150 g per 24 hours (170 to 510 kcal), which should be managed with subcutaneous or intravenous insulin provided based on blood glucose
determinations taken on a regular basis and algorithm-based insulin doses. It should be emphasized that, the insulin administered subcutaneously, either as a continuous intravenous infusion or as a bolus intravenous dose, has a serum half-life of approximately 5 to 7 minutes. The same principles may be applied to patients receiving substantial amounts of glucose in the peritoneal dialytic regimens, where insulin is often best provided in the dialysis solution. Thus, for some cases, such as a patient undergoing both peritoneal dialysis and PN or EN, insulin is given via multiple routes to cover the administration of glucose from various sources to link the insulin administration to the source of exogenous glucose. When hyperglycemia is severe because of severity of the stress response or severity of insulin deficiency (type 1) or insulin resistance (type 2), it is reasonable to employ continuous intravenous insulin and close blood glucose monitoring to quickly establish glucose homeostasis, whatever the source of exogenous glucose.

Goals of Nitrogen Balance

Achieving positive nitrogen balance is an unrealistic goal in the critically ill early in the clinical course. Rather, the principal aim of nutritional intervention is to support the protein synthetic response to injury and, therefore, narrow the negative nitrogen gap (where output exceeds input) that occurs during severe metabolic stress. Even when the metabolic stress has subsided, it should be recognized that nutritional rehabilitation of the moderate-to-severe malnourished patient occurs at a limited rate equivalent to approximately 1 kg of body weight per week, and generally much of this repletion will occur outside the hospital after discharge. This estimation is based on a maximum rate of repletion of a positive nitrogen balance (i.e., approximately +5 g per day) that represents 150 g of lean tissue (hydrated protein) and a calorically equivalent amount of fat (13 g) per day. Weight increases above this rate of repletion can only reflect increases in TBW.

Finally, it should be mentioned that when expending the effort to obtain a 24-hour urine collection, additional laboratory measurements should be performed on this specimen, such as for the determination of creatinine excretion and certain electrolytes (sodium, potassium, and chloride). In this way, important additional clinical information may be provided, including creatinine clearance, urea clearance, fractional excretion of sodium, and quantification of electrolyte losses, among other possible data that may be used in the clinical and nutritional/metabolic care of critically ill patients.
EVIDENCE-BASED GUIDELINES FOR NUTRITIONAL SUPPORT THERAPIES

In 2009, the Society of Critical Care Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN) developed and copublished “Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient” [148,149]. The last statement of the introduction of this document is noteworthy: “Delivering early nutrition support therapy, primarily using the enteral route, is seen as a proactive therapeutic strategy that may reduce disease severity, diminish complications, decrease length of stay in the ICU, and favorably impact patient outcome.” Of the 12 categories or conditions (sections A through L), 9 sections related to EN, 2 sections on PN, and 1 section (L) relating to end-of-life situations. It is the authors’ opinion that this document is unfortunately biased against the potential utility of PN in many circumstances. The assessment system applied in the guidelines consisted of “Levels of Evidence” and “Grades of Recommendation.” “Levels of Evidence” were from I to V, with “Level I” being the strongest evidence and “Level V” being the weakest evidence. The “Grades of Recommendation” were from A to E, with “A” being the highest and “E” being the lowest. If, for example, one scores the grades according to a quality point average (QPA) as applied in education with $A = 4.0$, $B = 3.0$ ... $E = 0.0$, the evidence is poor for both EN and PN. For example, in the SCCM/ASPEN 2009 guidelines, the QPA for all EN sections was 1.21 and the QPA for all PN sections was 1.25. We selected three controversial statements in the guideline:

A3. “EN is the preferred route of feeding over parenteral nutrition (PN) for the critically ill patient who requires nutrition support therapy. Grade B”

The statement is correct, and fits Dr. Dudrick original thesis “if the guts works, use it,” but the principal rationale for its preference, that is, reduced infectious morbidity is misidentified. Although previous studies have shown this association to be true, the premise overlooks the importance of blood glucose control and caloric intake in these studies. Invariably, the PN group in many of the supporting studies received significantly more calories than the EN group and, consequently, had higher blood glucose values that clearly increase infectious complications. This is not surprising because EN is often not well tolerated in eucaloric amounts as PN, and is frequently interrupted for various clinical maneuvers or diagnostic tests in the critical care setting. As well, the
insulin required to maintain glucose homeostasis is greater for parenteral compared to enteral glucose. Furthermore, the data supporting this statement was essentially derived before the subsequent eras of reduced energy provision and tight glucose control in the critically ill.

G1. “If the patient is deemed to be a candidate for PN, steps to maximize efficacy (regarding dose, content, monitoring, and choice of additives) should be used. Grade C”

In accordance with the thesis of “do no harm,” it would seem intuitively obvious that the safety and efficacy of PN would be accomplished by optimizing the formulation. A “Grade C” recommendation diminishes the importance of dosing nutrients, which unfortunately, is associated with a long history of overfeeding and its attendant complications. In the same section (G6), the use of extemporaneously prepared parenteral glutamine is given the same “Grade C,” despite the fact that such an additive is classified as a “HIGH RISK” compounded sterile preparation by the USP [20].

H3. “Serum phosphate levels should be monitored closely and replaced appropriately when needed. Grade E”

The literature is replete with data on the importance of serum phosphate levels is the critically ill, especially with respect to the risks associated with hypophosphatemia on myocardial performance and respiratory function [149]. Moreover, the provision of hypertonic glucose in a PN admixture produces a supraphysiologic increase in serum insulin levels that will cause significant intracellular shifts that may produce life-threatening hypophosphatemia in susceptible patients. A “Grade E” recommendation is inappropriate in this circumstance. Also, in 2009, the European Society of Parenteral and Enteral Nutrition produced “Guidelines on parenteral nutrition: intensive care” [150]. Seventeen statements (categories or conditions) are included, and there are three Grades of Recommendation (A, B, and C) with the strongest evidence being “Grade A” versus the weakest evidence with a “Grade C.” Only two statements received “Grade A.” We selected three controversial statements in this guideline.

Under “Requirements”

“During acute illness, the aim should be to provide energy as close as possible to the measured energy expenditure in order to decrease negative energy balance. Grade B”
In the ICU setting, particularly during the early phases of critical illness, hypocaloric regimens often seem to be most prudent. Maintenance of normal blood glucose values should take precedence over energy balance in most critical care settings, and then once achieved, judicious increases in calories can commence. “In the absence of indirect calorimetry, ICU patients should receive 25 kcal/kg/day increasing to target over the next 2–3 days. Grade C”

As already stated, caloric intakes in the ICU should be advanced slowly after the initial provision of 50% of energy and 1.0 to 1.2 g protein per kg to avoid hyperglycemia and infectious morbidity. As stated earlier, for most patients, providing 25 kcal/kg/d is sufficient to support the protein synthetic response to metabolic stress. The guideline, as stated earlier, implies that 25 kcal/kg/d is the starting point, when in fact, for most adult patients, it is the target range [151], and is gradually reached after initiating lesser amounts of calories from the outset.

Under “Amino Acids”

“When PN is indicated in ICU patients the amino acid solution should contain 0.2–0.4 g/kg/day of L-glutamine (e.g., 0.3–0.6 g/kg/day alanyl-glutamine dipeptide). Grade A”

Although there is a commercial product in Europe that is available to provide glutamine supplementation, a recommendation of Grade A seems to be overly optimistic. This is especially true given the recent assessment of L-glutamine in the ICU of an “area of uncertainty” from one of the leading investigators in the field [151]. Thus, such a recommendation seemed premature at the time, and, subsequently, more recent studies have shown this not to be the case [99–103].

At this time, the data is unclear for several reasons. First, the guidelines and methods of assessment must be standardized between organizations. Second, “mining of data” from past studies, many of which are significantly flawed with respect to design and endpoints, cannot yield meaningful guidelines, despite the use of statistical tools, such as meta-analyses. Third, critically ill patients are not homogeneous. As recently pointed out, EN is contraindicated in 10% to 15% of ICU patients; there are very few well-designed, randomized controlled studies of PN efficacy, and preexisting malnutrition, combined with numerous pathophysiologic factors in ICU patients which greatly complicate the role of nutrition support [151, 152].

Thus, it seems that to definitively address the evidence for nutrition support therapy in the ICU setting will require designing better studies in the future rather than the current methods to rehash old data from a previous era using statistical tools. A major emphasis should clearly be on the design (randomized controlled trial, sufficient power, APACHE score,
etc.) and specific endpoints for future studies to answer the question of the impact of nutritional therapy in the critically ill on morbidity and mortality and clinical outcome. For example, we now have a series of multicenter studies that have focused on the potential role of early (within 72 hours of ICU admission) and adequate energy (>50%, but <110% of energy requirements) and protein (at least 1.2 g/kg/d), immunonutrients, PN versus EN, and so on. Great progress has been made in the quality of such studies, but to have a truer understanding of the role of nutrition support therapy in the critically ill, more work needs to be done to ensure that nutrition support is provided to those patients most likely to derive clinical benefits, with more precise doses of nutrients and means of delivery, and done so in a timely manner.
CONCLUSIONS

Nutritional and metabolic support is an essential component of the clinical care of critically ill patients. However, if applied in an overly aggressive manner without considering the nutritional status, amounts of nutrients, route of administration, and the clinical condition of the patient, significant iatrogenic complications may occur and little clinical benefit can be expected. Thus, nutritional support of the critically ill must be carefully integrated into the overall clinical care of the patient, with specific and measurable outcome measures in order to obtain the maximum benefits of this important therapy.

INTRODUCTION

For the critically ill patient, the constant barrage of multiple physiologic derangements quickly leads to malnutrition. The hypermetabolic response to stress changes the nutritional requirements of these individuals, but failure of the various organ systems complicates the issue. Renal, hepatic, and pulmonary function must be considered when prescribing nutritional therapies in the intensive care unit (ICU). This chapter discusses the metabolic abnormalities associated with these disease processes, the nutritional assessment of the patient in organ failure, and proposes evidence-based guidelines for nutritional support in these disease-specific populations.
RENAL FAILURE

Despite many recent advances of medical therapy, management of the critically ill patient with renal failure remains challenging. Acute kidney injury (AKI) is associated with an overall mortality rate of 50% to 60%, depending on its derivations and comorbid conditions [1]. Hypotension and hypovolemia, secondary to excessive fluid losses, inadequate fluid replacement, or decreased cardiac output are common causes of renal failure among the critically ill. Factors such as shock or sepsis and exposure to nephrotoxic drugs can also predispose patients to renal dysfunction [2]. Early diagnosis and restoration of circulating blood volume to the kidneys may decrease the risk of permanent damage; however, the course to renal recovery is often a complicated one. The patient with chronic kidney disease (CKD) is also at increased risk for morbidity, because these patients often have protein–calorie malnutrition (PCM) at baseline. Moreover, the nutritional support of the patient on renal replacement therapy will offer a unique challenge to the critical care practitioner.

Malnutrition and Metabolic Abnormalities of Renal Disease

In general, renal failure is characterized by altered nutrient metabolism, defective metabolic waste excretion, inadequate nutrient intake, and excessive nutrient losses. Inflammatory cytokine levels are increased in patients with advanced CKD, and this can result in decreased serum albumin concentrations, decreased appetite, and weight loss [1]. In fact, malnutrition and inflammation may occur in approximately 30% to 70% of patients with CKD [3]. For these patients, PCM is most often the result of hypercatabolism, poor dietary intake secondary to uremia-induced gastroparesis, poor-tasting highly restrictive diet prescriptions, and medications with gastrointestinal side effects. The overall effect of these derangements results in protein-energy wasting and cachexia, which is closely associated with morbidity and mortality, particularly among patients with advanced CKD [4]. In addition, 10% to 30% of critically ill patients experience AKI, and therefore, represent a significant portion of critically ill patients who require nutrition support [5].

Common metabolic abnormalities associated with AKI include glucose
intolerance, impaired lipolysis, increased protein catabolism, decreased protein synthesis, fluid and electrolyte imbalances, and metabolic acidosis. Catabolic hormones increase glycogenolysis and gluconeogenesis of acutely ill patients, while renal gluconeogenesis and glucagon clearance is decreased in the setting of AKI [5]. This combination of derangements renders patients with AKI particularly prone to hyperglycemia and insulin resistance during critical illness. This is coupled with decreased renal insulin clearance that necessitates close monitoring of blood glucose to avoid hyper- or hypoglycemia. Decreased activity of lipolytic enzymes, such as hepatic triglyceride lipase and lipoprotein lipase, may reduce clearance of parenterally infused lipid emulsion by as much as 60% in patients with AKI compared to subjects with normal renal function [6]. Adequate energy provision may thus be hindered by altered carbohydrate and fat metabolism. Energy requirements of patients with AKI are best met with formulas providing mixed substrates with 10% to 15% of total calories from protein, 55% to 70% from carbohydrates, and 20% to 30% from fat [7].

Several factors contribute to increased protein catabolism and overall negative nitrogen balance of patients with AKI. One aspect of the metabolic response to injury is the breakdown of skeletal muscle proteins for use as an energy source, via an increase of hepatic gluconeogenesis, and for synthesis of acute-phase proteins. Metabolic acidosis, which commonly occurs during renal failure, can trigger skeletal muscle protein breakdown as well. Reduction of muscle protein synthesis among this population has been linked to diminished cellular uptake of glucose and amino acids secondary to insulin resistance, altered cellular ion transport mechanisms, and defective intracellular synthesis [5].

Energy and Protein Requirements of Patients with Renal Disease

Although AKI alone does not result in hypermetabolism, energy requirements are affected by other comorbidities during acute illness and by prior nutritional status. Evidence using indirect calorimetry suggests that energy expenditure of critically ill patients with AKI only increases up to 130% of normal. Thus, the recommended energy delivery for critically ill patients with AKI is similar to those without AKI at 25 to 30 kcal/kg/d [5,8]. Establishing appropriate goals for protein delivery requires consideration of degree of illness, degree of renal insufficiency, and mode of renal replacement therapy. Patients with CKD with modest renal function who are not on intermittent hemodialysis (HD) only require 0.6 to 0.8 g/kg/d of protein. Patients with AKI on intermittent HD can achieve a positive nitrogen balance with 1.5 g/kg/d, while those with CKD receiving maintenance HD require protein of doses at 1.2
g/kg/d. For critically ill patients with AKI the recommended protein doses is 1.2 to 2 g/kg/d of actual body weight be provided [9]. Protein requirements during continuous renal replacement therapy (CRRT) are greatly increased to 1.8 to 2.5 g/kg/d due to the associated level of stress in addition to protein losses in the effluent [1,5]. These protein requirements illustrate the significant role that the mode and dose of renal replacement play on the nutritional status of critically ill patients. Recommendations for energy and protein intake are summarized in Table 214.1.

Comments:
- Protein dose should not be restricted to avoid initiation of HD or CRRT.
- Protein and amino acid loss during CRRT ranges from 5 to 10 g and 10 to 15 g/d.
- Protein loss during HD ranges from 10 to 13 g/session.

Data and comments compiled from Refs. [1,5,8–12].

AKI, acute kidney injury; CKD, chronic kidney disease; HD, hemodialysis; CRRT, continuous renal replacement therapy.

**Metabolic Abnormalities and Renal Replacement Therapy**

Provision of protein can be complex in the setting of AKI and critical illness as protein needs are significantly increased while clearance of urea may be decreased. Although lowering the amount of protein delivered
may avoid the development of azotemia, current recommendations suggest that protein doses should not be restricted in an attempt to avoid initiation of HD or CRRT [10]. The protein requirements as previously discussed are in part due to nitrogen loss associated with dialysis. In CRRT, there is a loss of at least 0.2 g amino acids per L of ultrafiltrate (up to 10 to 15 g amino acids per day), and of 5 to 10 g per day of proteins. In contrast, protein losses range from 10 to 13 g per HD session [11,12]. In addition, these patients tend to be severely volume overloaded with fluid shifting to the extravascular space because of capillary leak and hypoalbuminemia. Under these circumstances, it is advised that the clinically appropriate protein dose be met, even if giving extra fluid seems to be counterintuitive, as attaining nitrogen balance for the repletion and reversal of the effects of low serum albumin is of paramount importance in the care of these patients.

While preparing a nutrient prescription, consideration should be given to typical glucose content of the dialysate, as this may make a significant contribution to the caloric load of patients already exhibiting some degree of glucose intolerance. Dextrose-containing CRRT dialysate containing 1.5% dextrose can contribute up to 600 glucose calories during a 10-L per day dialysis infusion [13].

Close monitoring of fluid status is crucial for the maintenance of adequate intravascular volume and renal perfusion. Fluid is typically restricted to 1 to 1.5 L per day in nondialysis anuric or oliguric patients. Sodium often needs to be restricted for these patients as well. In this situation concentrated enteral or parenteral formulas are often used to meet daily nutrient requirements. Renal replacement therapy, particularly CRRT, allows for a liberalization of fluid provisions and often makes it easier to deliver full protein and energy requirements. Finally, sodium intake can be liberalized in the setting of CRRT to help correct acid-base or electrolyte abnormalities.

Serum electrolyte levels often fall outside of the normal range depending on renal excretion, extent of catabolism, and type and duration of dialysis [14]. Increased catabolism of skeletal muscle protein releases phosphorus, potassium, and magnesium and may elevate serum electrolyte concentrations. Therefore, patients with AKI or CKD who are not receiving any form of renal replacement therapy typically need their intake of these electrolytes to be limited [5]. For patients on dialysis, it is important to account for the timing of blood draws in relationship to dialysis as this can have a remarkable effect on the measured serum levels of electrolytes. For example, serum potassium can be significantly
decreased during HD, depending on the potassium concentration of the dialysate, duration and modality of HD, and baseline serum potassium concentrations. Conversely, there is a rapid shift of potassium from the intracellular to extracellular compartments following HD that can result in up to a 70% increase of serum potassium within 6 hours [15]. In general, patients receiving HD usually require much lower amounts of electrolyte supplementation, especially between treatments, compared to patients receiving CRRT who often require repletion of sodium, potassium, calcium, magnesium, or phosphorus as these are filtered through this modality. Phosphorus in particular is likely to require repletion, because it is much more efficiently cleared by CRRT compared to HD [8]. This is illustrated in a recent report where nearly 69% of 760 critically ill patients undergoing CRRT for AKI experienced hypophosphatemia. Further, they found that the occurrence of hypophosphatemia during CRRT therapy was independently associated with a 1.5-fold higher 28-day mortality [16]. Patients on CRRT therefore may require the addition of a phosphate source to their dialysate as well as daily monitoring of serum phosphorus so that adequate repletion can be provided. Conversely, depressed serum ionized calcium levels are a common result of uremia that is accompanied by hyperphosphatemia. In this situation supplementation of calcium can be used to prevent the release of calcium from the bone.

The dangers of undershooting electrolyte needs for a malnourished CKD population cannot be overstated. Introducing a carbohydrate load by the parenteral or enteral route to a malnourished patient stimulates insulin production, cellular anabolism, and shifts potassium, magnesium, and phosphorus into the intracellular space [17]. The severe decline of serum electrolyte levels with resultant clinical complications is referred to as refeeding syndrome. A series of four patients with CKD who developed significant hypophosphatemia after starting PN due to inadequate electrolyte provisions demonstrates that this problem can even occur when renal function is significantly impaired [18]. It is therefore recommended that dextrose infusions be started gradually, serum electrolyte monitoring be done at least once daily, and abnormalities be corrected appropriately.

It is our practice to provide multivitamin preparations standard to enteral and parenteral formulas for most patients in the ICU with AKI and CKD who are receiving CRRT. However, since vitamins and trace elements may be lost in significant amounts during dialysis [14], it has been suggested that supplementation of folic acid, thiamine, and selenium be provided to patients with AKI undergoing CRRT [5]. We generally do not measure blood levels of vitamins or trace elements unless the patient is at risk for deficiency or excess as interpretation of results is often difficult as concentrations may be affected by the acute-
phase response. An exception to this approach is for patients with AKI who are not on dialysis. For these patients supplementation with vitamins C and A should be reduced or eliminated, if possible, as evidence suggests that vitamin C in amounts greater than 100 mg per day can lead to oxalate accumulation with renal injury. Likewise, if signs of vitamin A toxicity are observed, daily provision may need to be withheld.

Nutrition Assessment During Renal Disease

Along with other disease states associated with critical illness, early initiation of nutritional support (i.e., within 24 to 48 hours) is recommended [9]. Unfortunately, common measures of nutritional status, such as serum albumin, prealbumin, serum transferrin, weight changes, and anthropometrics are not reliable for this patient population who is typically volume overloaded with metabolic derangements associated with the inflammatory processes of critical illness. Despite this, serum albumin is considered the strongest laboratory predictor of mortality for hospitalized patients with renal failure and should be considered as an important biomarker in the identification of patients who may benefit from nutritional support [19]. Daily monitoring of weight and intake and output records can help to assess fluid balance in these individuals. It is essential to use a dry weight (i.e., free of edema or ascites) when examining alterations in weight status. The dry or adjusted body weight of a renal patient may then be used to more closely estimate daily nutrient needs.

Enteral and Parenteral Formulations for Renal Disease

A wide array of enteral nutrition (EN) products has been designed for patients in varying stages of renal disease (Table 214.2). Standard enteral formulas are recommended for most critically ill patients with renal failure. The formula should be changed to a specialty formulation if severe electrolyte abnormalities are present [9]. Formula selection may also depend largely on the individual’s fluid allowance, as a more concentrated enteral formula is usually preferred in the setting of hypervolemia (i.e., 2 kcal per mL). For patients with AKI in whom CRRT has not been initiated, a formula containing only essential amino acids and histidine with little or no vitamins, minerals, and electrolytes may be appropriate. Products with reduced levels of protein, phosphorus, potassium, magnesium, and vitamin A are useful for patients with chronic renal insufficiency who are not on dialysis. Moderate protein formulas with low electrolyte content are often indicated for patients receiving intermittent dialysis treatments. It is best to initiate tube feedings at a slow rate in this population and advance the feeding rate gradually to prevent osmotic diarrhea. Because patients on CRRT
demonstrate improved clearance of nitrogenous wastes, fluid, and electrolytes, standard enteral formulas may be used in addition to protein supplements in order to meet protein requirements. In this case, selection likely depends more on accompanying clinical conditions than on renal status. For example, a low-carbohydrate formula may be more appropriate for the CRRT patient with glucose intolerance than the typical calorically dense renal formulas.

Delayed gastric emptying related to dialysis treatment, diabetes, high blood urea nitrogen levels, hyperglycemia, or postoperative
gastrointestinal complications can lead to enteral feeding intolerance in patients with renal failure. Parenteral nutrition (PN) is indicated only when the enteral route cannot safely be used to fully meet daily nutritional requirements. For patients who are normal or mildly malnourished, this should occur 7 to 10 days following ICU admission, while earlier initiation should be considered for those who are severely malnourished [9]. In most cases a standard 10% amino acid solution can be used to prepare PN; however, when fluid volume restriction is necessary a 15% amino acid solution should be considered to provide a maximally concentrated parenteral formula.

**Summary of Nutritional Recommendations for Patients with Renal Disease**

Primary efforts of the caregiver should be directed toward management of the various nutritional and metabolic disorders commonly associated with renal failure. Adequate nutrient provision may optimize renal function, improve nutritional status, and increase the chances of survival for critically ill patients with AKI. Protein and energy requirements of critically ill patients with renal failure are similar to those without renal failure, with the exception of protein needs which are dictated by the mode of renal replacement [9]. Predictive equations, indirect calorimetry, or simple dry weight-based equations (25 to 30 kcal/kg/d) may be used to determine energy needs for critically ill patients with renal failure [5,8]. Serum electrolytes should be monitored daily with additives adjusted on an individual basis. Standard vitamins and trace minerals can safely be provided to most patients with renal failure in the ICU. Fluid allowances for nondialyzed or HD patients are based on 24-hour urine output with an additional 500 mL for insensible losses. Those undergoing CRRT should be permitted sufficient fluid for provision of full nutritional support.
As the central regulatory organ of the body, the liver is responsible for the metabolism, storage, activation, transport, and synthesis of many vital nutrients. Biochemical reactions fundamental to carbohydrate metabolism such as glycogenesis and gluconeogenesis are carried out in the liver. Albumin, transferrin, prealbumin, and prothrombin are a few of the major serum proteins generated by the liver. Fatty acid oxidation as well as the production of bile salts, triglycerides, and cholesterol for lipid absorption and transport is part of the normal hepatic function. The liver is also responsible for the catabolism of various potentially toxic substances including ammonia, alcohol, and acetaminophen. Liver damage can lead to the disruption of many of these processes; however, due to hepatic reserve functional capacity, dysfunction is not usually seen until 80% to 90% of the liver cells have been injured [20].

A number of insults can initiate the cellular degeneration of acute or chronic liver disease. Viral infection, alcohol use, medications or other hepatotoxic agents, cardiac shock, chronic cholestasis, metabolic disorders, and autoimmune diseases are all potential instigators of liver injury. The damage can be so sudden and severe that it results in fulminant hepatic failure (FHF), a rare disease involving extensive liver necrosis and often culminating in death. Complications of FHF include metabolic abnormalities such as hypoglycemia or acidosis, hemodynamic instability, cerebral edema, sepsis, immunosuppression, and the hepatorenal syndrome. Treatment of FHF often involves nutritional intervention and while there are no randomized controlled studies to assess the benefits of these therapies for this population, the 2009 ESPEN Clinical Guidelines on Parenteral Nutrition state that PN is a safe second-line option to adequately feed these patients in whom EN is insufficient or impossible [21].

Patients with acute hepatitis tend to be highly catabolic in the setting of severe gastrointestinal distress. Nausea, vomiting, and anorexia with occasionally concurrent acute pancreatitis may preclude adequate oral intake. Short-term nutrition support is often necessary until causes of the acute injury to the liver have been identified and treated.

Chronic liver diseases are characterized by repeated episodes of necrosis, followed by hepatocyte regrowth, formation of connective scar tissue and in severe cases the development of cirrhosis. The resulting disruption of normal hepatic structure increases resistance of blood flow through the liver and leads to portal hypertension, which can be characterized by esophageal varices with gastrointestinal bleeding, splenomegaly, ascites, hypoalbuminemia and hepatic encephalopathy
Malnutrition has been documented for most hospitalized patients with alcoholic liver cirrhosis [22]. Because of the association between PCM and poor clinical outcome these patients are often given PN, EN, or oral nutritional supplements [23,24]. It is important to note that the presence of esophageal varices or ascites does not preclude the use of small bowel nasoenteric tube feeding for malnourished cirrhotic patients [25]. Several controlled trials using EN in this population have demonstrated improvements of liver function tests, nutritional status, nitrogen balance, length of hospitalization, and overall prognosis [26–28]. The achievement of positive nitrogen balance did not have a negative impact on HE, azotemia, edema, or ascites among the study groups.

**Malnutrition and Metabolic Abnormalities of Liver Disease**

Malnutrition during acute or chronic liver disease is the result of a combination of factors. Inadequate provision of nutrients, the hypermetabolic state of cirrhosis, the diminished synthetic capacity of the liver, and the impaired absorption of nutrients are the main factors that disrupt the metabolic balance of cirrhotic patients [29]. Specifically, a decrease of oral intake is common in the patient with prolonged gastrointestinal distress, early satiety secondary to ascites, or excessive alcohol consumption. Maldigestion and malabsorption leading to steatorrhea is often seen with cholestasis or chronic pancreatitis. Impaired glycogen synthesis and storage as well as decreased hepatic degradation of stress hormones lead to the preferential use of lipid and protein reserves for gluconeogenesis [30]. Insulin resistance and glucose intolerance are usual complications of early liver failure. Hypoglycemia can occur during decompensated cirrhosis or FHF as a result of hepatic glycogen depletion and impaired gluconeogenesis.

Hepatic steatosis with concurrent depletion of adipose tissue stores is a frequent consequence of the imbalance between lipid uptake, fatty acid oxidation, and the release of lipoproteins by the damaged liver. It is important to note that hepatic steatosis is often preventable by avoiding overfeeding. Lipids are a moderate source of energy in EN supplement designed for use in liver failure patients. IV lipids are also metabolized well by critically ill patients with hepatic failure when given in amounts that do not exceed their energy requirements. This was demonstrated by Druml et al. who found no significant differences of uptake, hydrolysis, or oxidation of a 20% IV lipid emulsion in septic patients with hepatic
failure compared to healthy controls [31].

Altered protein metabolism is by far the most challenging aspect of providing nutrition therapy to the critically ill patient with liver disease. Cirrhosis has long been established as a catabolic disease, with unremitting protein degradation and inadequate resynthesis leading to depletion of visceral protein stores and muscle wasting [32]. Skeletal muscle autophagic proteolysis and myostatin expression (an inhibitor of protein synthesis) are increased with cirrhosis and believed to contribute to anabolic resistance. A recent prospective study performed to determine the mechanisms of sarcopenia with alcoholic cirrhosis found that impaired mTOR1 signaling increased autophagy of skeletal muscle and that this process is acutely reversed by an oral mixture of branched-chain amino acids (BCAAs) enriched with leucine [33].

Under ordinary circumstances, the skeletal muscle takes up circulating BCAAs for the synthesis of glutamine and alanine, amino acids that are released into the bloodstream and taken up by the liver for use in hepatic gluconeogenesis. Glutamine is also a carrier for ammonia, a potentially toxic by-product of protein metabolism. Ammonia is normally converted into urea by the liver and excreted by the kidneys. As liver function declines, uptake of serum glutamine is diminished and the degradation of ammonia into urea is impaired. In this case, excess serum glutamine and ammonia is diverted to renal pathways for direct excretion by the kidneys.

Adequate protein intake is therefore essential for the liver patient not only for the provision of energy by gluconeogenesis, but also for the preservation of skeletal muscle mass and the prevention of HE. The clinical practice of protein restriction for patients with liver damage is common, for fear of precipitating or worsening central nervous system changes associated with HE. Several protein-related theories have been proposed regarding the development of HE, although it is of significance that the occurrence of encephalopathy has not been observed to directly correlate with protein intake of cirrhotic patients [34]. Intravenous protein solutions with higher concentrations of BCAAs have been developed for use in liver disease based on the following hypothesis. As the use of BCAAs by skeletal muscle increases, serum levels decrease. An imbalance in plasma levels of aromatic amino acids (AAA) phenylalanine, tyrosine, and tryptophan and BCAAs and their BCAA/AAA ratio enhances brain AAA uptake and subsequently disturbs neurotransmission. These alternative neurotransmitters compete with actual neurotransmitters for binding sites and disrupt normal central nervous system function to cause symptoms of HE [35].

Elevated serum ammonia concentrations have also been implicated in the pathogenesis of HE. Ammonia metabolites such as glutamine in cerebrospinal fluid have been correlated with the severity of
encephalopathy [36]. Plauth et al. evaluated differences of serum ammonia levels between enterally and parenterally fed cirrhotic patients’ status post-transjugular intrahepatic portosystemic shunt placement [37]. The small intestinal metabolism of enterally fed glutamine was found to produce significantly greater serum ammonia levels than the direct systemic infusion of parenterally fed glutamine. This suggests that PN may allow for a safer way to provide protein to encephalopathic patients. Enteral or parenteral administration of glutamine, however, is not recommended for patients with moderate to severe liver disease [38].

**Energy and Protein Requirements During Liver Disease**

Recently published clinical guidelines for critical illness suggest that, when available, indirect calorimetry should be used to determine energy requirements in all critically ill adults [9]. Guidelines that specifically address nutrition support in liver disease recommend that resting energy expenditure (REE) should be increased by a factor of 1.3 in patients with alcoholic steatohepatitis, cirrhosis, and acute liver failure [21]. If measurement of REE is not available, the target for energy intake in critically ill adults should be 25 to 30 kcal/kg/d [9]. A dry or usual weight should be used instead of actual weight in predictive equations to determine energy and protein goals in patients with cirrhosis and hepatic failure as fluid overload, due to complications of ascites, intravascular volume depletion, edema, portal hypertension, and hypoalbuminemia, can result in the overestimation of needs [9]. Nutrient formulas are generally prepared with mixed substrates to provide 10% to 15% of total calories from protein, 55% to 70% from carbohydrates, and 20% to 30% from fat. Greater proportions of fat should be considered for patients with glucose intolerance as long as the fat is not entirely from oils that are high in n-6 polyunsaturated fatty acids [21].

Recommended protein goals for alcoholic steatohepatitis and cirrhosis range from 1.2 to 1.5 g/kg/d [21]. In acute or subacute liver failure protein dosing should be lowered slightly to 0.8 to 1.2 g/kg/d. For cirrhotic patients with HE, protein should be given at the lower end of this range only until the causes of encephalopathy have been identified and treated. In these instances, once patients show signs of improvement, protein should be advanced as tolerated to goals of 1.2 to 1.5 g/kg/d to help maintain nitrogen balance [39]. In nearly all cases the standard protein or amino acid formula is advised [9]. Recommendations for energy and protein intake are summarized in **Table 214.3**.

**Comments:**
- If indirect calorimetry is available, provide REE × 1.3 for energy requirements.
- Use standard protein and amino acid formulations when other measures to treat HE are initiated.
- Use branched-chain amino acids if HE does not resolve with treatment.
- Increase protein dose once HE resolves to promote a positive nitrogen balance.

Data and comments compiled from Refs. [9, 21, 39].

HE, hepatic encephalopathy.

A Cochrane review from 2015 looked at 16 randomized clinical trials that enrolled 827 patients with either overt (12 trials) or minimal (four trials) HE. These studies were performed with oral (eight trials) or intravenous (seven trials) BCAA products as the protein source [40]. BCAA had a beneficial effect on HE (RR 0.76, 95% CI 0.63 to 0.92), though sensitivity analyses found no difference between BCAA compared to lactulose and neomycin (RR 0.66, 95% CI 0.34 to 1.30). It is unclear if these results are applicable to the critically ill and it is because of this that the aforementioned guidelines for critically ill patients state that there is no evidence of further benefit of BCAA formulations on coma grade for the ICU patient with encephalopathy who is already receiving first-line therapy with luminal-acting antibiotics and lactulose [9]. In addition, few published studies exist to date, comparing BCAA-enriched PN to parenteral solutions containing standard amino acids [41–43]. No differences in outcomes were noted in each of these studies. This is opposed to the guidelines for liver disease that recommend BCAA formulations for patients with stage III and IV HE [21]. Our approach is to use these special formulations when patients do not improve after
instituting measures to reverse and treat HE and following the reduction of the protein dose to 0.8 g/kg/d for 24 to 48 hours. 

As is the case in most patients with critical illness, EN is the preferred route of nonvolitional feeding in those with liver disease [9]. IV glucose at a dose of 2 to 3 g/kg/d should be given when EN cannot be given for 12 or more hours because of the risk of hypoglycemia from hepatic glycogen depletion and impaired gluconeogenesis [21]. For patients with FHF, IV glucose at this dose should be given prophylactically to prevent hypoglycemia. PN should be considered when enteral feeding cannot be started within 72 hours for patients with cirrhosis or HE with an unprotected airway [21]. It should be started immediately for patients with alcoholic steatohepatitis or cirrhosis who have moderate to severe malnutrition. It should be started for patients with acute liver failure when it is anticipated that EN cannot be started within 5 to 7 days.

**Nutrition Assessment During Liver Disease**

Traditional parameters of nutritional status such as weight loss and depletion of visceral protein stores are frequently masked among liver failure patients by the presence of ascites or edema. Serum albumin, prealbumin, and transferrin levels are more reflective of disease-related intravascular volume expansion and increased protein catabolic rate than the severity of nutritional deficit. Despite this, albumin remains an important marker of PCM among liver patients. Because the upper extremities tend to escape the fluid retention often seen in liver patients, midarm muscle circumference and triceps skinfold measurement is considered to be the most accurate tools for nutrition assessment in this population. Severe reduction of midarm muscle circumference and triceps skinfold measurement, suggestive of muscle mass and body fat depletion were found to be independent predictors of survival in a study of 212 hospitalized cirrhotic patients. In this study, Alberino et al. also advised the inclusion of upper-arm anthropometry to improve prognostic accuracy of the Child-Pugh score, a commonly used classification of the severity of liver disease [44]. Recent investigations have focused on the detection of those nutritional parameters most indicative of PCM and predictive of survival of liver failure patients. Computer tomography can be used to quantify skeletal muscle mass at the third lumbar spine and standards using this technique have been developed to define sarcopenia, the age-related decrease of muscle mass. Using this method, 112 patients with cirrhosis who were consecutively evaluated for liver transplantation by investigators who found that muscle wasting was associated with mortality independently of the degree of liver dysfunction as determined the by Child Pugh and MELD scores [45]. Similar findings have been confirmed by others [46]. Until this technique becomes readily available,
a comprehensive analysis of all available data, including physical examination, anthropometric measurements, and laboratory values, may therefore be the best determinant of nutritional status during liver disease.

**Liver Transplantation**

Currently, the best therapy for unsalvageable liver failure is orthotopic liver transplant (OLT). It is of the utmost importance to assess the nutritional status of patients who are candidates for OLT as malnutrition has been shown to contribute to an increase of postoperative infection rates, ventilator dependence, hospital length of stay, and a decrease of 1-year survival [47]. In a survey of 248 patients who had undergone OLT, 45% were found to have sarcopenia by CT and its presence was associated with a longer hospital stay (40 vs. 25 days), and more frequent postoperative bacterial infections (26% vs. 15%) [48]. Although these investigators did not find a relationship between sarcopenia and postoperative mortality, Masuda et al. did find that sarcopenia, which was noted for 47% of the 204 patients who underwent living donor liver transplantation, led to a twofold increase of mortality and a fivefold increase of the risk of developing sepsis following transplantation [49].

Perioperative nutritional support appears to reduce the risk of infection following OLT. A retrospective study comparing a historic cohort of patients who all received EN following living donor liver transplantation was compared to a group that only occasionally received tube feedings, found that the incidence of sepsis of 28.2% for the intermittently fed group was significantly higher than the 10.5% rate of those receiving regular nutritional support ($p = 0.03$) [49]. A randomized controlled trial of 36 patients undergoing living donor liver transplant compared early EN to an oral diet as tolerated and found a significant decrease of postoperative bacterial infections with the intervention (63.2% vs. 29.4%) [50]. A meta-analysis of seven randomized controlled trials involving 501 patients who received perioperative immunonutrition demonstrated a 49% lower risk of infectious and a 4-day shorter length of stay for those receiving immunonutrition [51]. Six trials used fish oil, glutamine, or arginine via the parenteral route while one trial used an enteral product combining all of these nutrients. Although this meta-analysis suggests immunonutrition may be of benefit, a moderately large randomized controlled trial of 101 patients comparing EN supplemented with fish oil, ribonucleic acid and arginine to standard tube feeding for at least 5 days following OLT did not demonstrate a difference of the incidence of postoperative infection (60% vs. 57%) [52]. None of these studies found nutritional support to affect postoperative mortality or hospital length of stay.
Repletion of lean body mass can be difficult following OLT. In a cohort of 53 patients where 33 (66.2%) were found to have sarcopenia prior to OLT, an additional 14 patients developed sarcopenia when followed for up to 19 months after transplantation [53]. No significant change of total-body protein, as measured by neutron activation, was seen after 1 year among the patients who participated in the trial of perioperative immunonutrition versus standard enteral feeding [52]. On the other hand, fat mass increases following OLT and likely contributes to the development of hyperglycemia and hyperlipidemia for some patients. Factors that appeared to contribute to the difficulty in attaining positive nitrogen balance include the postoperative elevation of REE that may occur for up to 1 month following transplantation [54] and an increase in the expression of myostatin that has been attributed to calcineurin inhibitors [53]. These observations illustrate some of the challenges that clinicians face when trying to improve the nutritional status of patients following OLT.

**Enteral and Parenteral Formulations for Liver Disease**

Enteral and parenteral formulas for use during liver failure are designed to normalize plasma amino acid concentrations and improve encephalopathic symptoms. There is currently one hepatic EN product that is calorically dense, has an increased ratio of BCAA/AAA, and has a low fat content (Table 214.2). Intravenous solutions for use during hepatic failure consist of 8% amino acids with 36% of total amino acids provided as BCAA (e.g., valine, isoleucine, and leucine) and only 2% as AAA (e.g., tryptophan, phenylalanine, and tyrosine). These include Aminosyn-HF (Hospira, Inc., Lake Forest, IL), Hepatasol (Clintec Nutrition, Deerfield, IL), and HepatAmine (B. Braun Medical, Inc., Irvine, CA).

A primary focus of the management of HE should be on treatment of its underlying causes. Dehydration, infection, electrolyte abnormalities, gastrointestinal bleeding, acid–base imbalances, and medications have been implicated as causing or contributing to the occurrence of encephalopathy among critically ill patients. Lactulose is the first-line therapy for hepatic HE. Lactulose may be supplemented with neomycin or rifaximin and intraluminal antimicrobials that work by reducing the burden of enteric flora that contribute to the metabolic by-products that lead to HE. In most acute cases, mental status improves with these interventions. When patients are refractory to these measures, protein intake should be reduced to the lower end of the therapeutic range.
Nutrition formulations with modified BCAA/AAA ratios should be considered when HE does not improve following these steps.

Summary of Nutritional Recommendations for Liver Disease

In devising a plan for nutritional management of the critically ill patient with liver disease, one must consider the nutritional status, etiology of the disease, and associated complications and metabolic abnormalities. Although direct measurement of lean body mass holds promise for accurately identifying patients at greatest nutritional risk, physical examination, upper arm and other anthropometric measurements, and laboratory values are currently the best determinants of nutritional status for patients with liver disease. Measurement of REE increased by a factor of 1.3 is the best method to determine energy requirements in alcoholic steatohepatitis, cirrhosis, and acute liver failure, but when this is unavailable a goal of 25 to 30 kcal/kg/d using dry body weight may be used [9,21]. Recommended protein goals are 1.2 to 1.5 g/kg/d for patients with alcoholic steatohepatitis and cirrhosis and 0.8 to 1.2 g/kg/d for those with acute or subacute liver failure [21]. For patients with HE, protein dosing should be reduced to 0.8 g/kg/d only until there is clinical improvement and BCAA-enriched formula should be considered when treatment of HE and reduction of protein dosing of standard formulations does not lead to clinical improvement [39]. Transition to standard formulations with protein goals of 1.2 to 1.5 g/kg/d should be done once HE resolves. EN is the preferred mode of nutrition support and may be administered via a gastric tube in the presence of esophageal varices. Nutrient formulas are generally prepared with mixed substrates to provide 10% to 15% of total calories from protein, 55% to 70% from carbohydrates, and 20% to 30% from fat. Sodium and fluid restriction are indicated with ascites or edema. Recommended daily allowances of vitamins, minerals, and trace elements are usually sufficient for this population, although additional supplementation of thiamine and folic acid is customary for patients with alcoholic cirrhosis. Although some reports have found that zinc supplementation may improve HE, a recent meta-analysis has questioned the efficacy of zinc as a routine therapy for this condition [55]. Intravenous glucose (2 to 3 g/kg/d) should be given when EN cannot be given for 12 or more hours as depletion of glycogen stores in this population quickly leads to protein breakdown for gluconeogenesis. Infusion of 10% dextrose solutions should be given prophylactically to patients with FHF to prevent hypoglycemia until full feeding by EN or PN, which can provide a more concentrated source of glucose and avoid fluid overload, is firmly established. PN should be considered within 72 hours when EN cannot be started in critically ill
patients with liver disease or those were at high risk for aspiration pneumonia. PN should be started immediately for patients with alcoholic steatohepatitis or cirrhosis with moderate to severe malnutrition and for those with acute liver failure who may not be able to start EN within 5 to 7 days. Table 214.4 outlines the summary of randomized controlled trials and clinical guidelines in liver disease.

**TABLE 214.4 Nutrition Support in Liver Disease: Summary of Controlled Trials and Clinical Guidelines**

- Protein restriction is not advised to reduce the risk of hepatic encephalopathy (HE) as it may paradoxically exacerbate this condition and may worsen nutritional status [9].
- Standard protein and amino acid preparations are indicated in most patients [9,21]. Branched-chain amino acid preparations for liver disease are therapeutically equivalent to lactulose or neomycin for HE [40]. The latter are recommended as first-line therapy [9].
- Branched-chain amino acid preparations for liver disease may be considered in grade III or IV HE [21].
- Enteral nutrition (EN) is the preferred feeding route [9]. Start PN within 72 h of ICU admission if EN cannot be started in unstressed, mildly malnourished patients or immediately in moderately or severely malnourished patients who cannot be fed enough by mouth or by EN [21].
- IV glucose (2–3 g/kg/d) should be given if EN cannot be given for 12 or more hours as depletion of glycogen stores quickly leads to protein breakdown with loss of lean tissue for gluconeogenesis [21].
- Infusion of 10% dextrose solutions should be given prophylactically to patients with fulminant hepatic failure to prevent hypoglycemia until full feeding by EN or PN can be started [21].
- Perioperative nutrition support reduces the risk of postoperative bacterial infections following orthotopic liver transplantation [50]. Parenteral immunonutrition reduces infectious complications and length of stay [51]. Enteral immunonutrition appears to be equivalent to standard formulas [52].
Optimal pulmonary function is essential to the maintenance of adequate nutritional status. Through the process of gas exchange, the lungs and supporting respiratory structures provide oxygen to vital tissues for nutrient metabolism. The respiratory system also plays a major role for the regulation of acid–base balance. Pulmonary injury or insufficiency can lead to malnutrition and dependence on mechanical ventilation of the critically ill patient. Acute respiratory distress syndrome (ARDS), characterized by severe progressive hypoxemia and mechanical ventilation, is a frequent result of trauma, sepsis, or surgery in the critical care setting. The patient with chronic obstructive pulmonary disease (COPD) may also undergo periods of acute exacerbation requiring intensive care. These two forms of the lung injury illustrates the spectrum of nutritional status encountered in the critical care setting with patient suffering from ARDS often being normal prior to hospitalization and those with COPD being at risk of having chronic disease related malnutrition [56]. Numerous randomized controlled trials have been published over the last several years that have helped clarify the utilization of nutrition support for these patients and will be discussed in this section.

Malnutrition and Metabolic Abnormalities of Pulmonary Disease

Malnutrition with COPD is the result of an imbalance between energy intake and utilization [57]. Hyperinflation of the lung with an associated decrease in abdominal volume can lead to anorexia, early satiety, and tube feed intolerance. Oral intake may be hampered by dyspnea and fatigue during meal times and impaired leptin regulation, a hormone that reduces food intake. An increase in energy consumption from COPD has been attributed to an increase in the work of breathing, tobacco use and medication (theophylline and β-blockers). Loss of lean body mass may occur as a result of disuse atrophy, tissue hypoxia from arterial hypoxemia, anabolic hormonal insufficiency or systemic inflammation as a result of recurrent infections and an imbalance of inflammatory cytokines. Currently interleukin (IL)-1β is felt to play a more important role than IL-6 or tumor necrosis factor (TNF)-α, as recent studies have not found elevated levels of these latter two cytokines that were
previously thought to participate in this process. Just as pulmonary disease influences the onset of malnutrition, poor nutritional status may significantly impair several structural and functional components of the respiratory system. Respiratory muscles display reduced efficiency and endurance during nutrition deprivation due to loss of muscle mass and depletion of energy reserves. Impaired respiratory muscle function may result in decreased ventilatory drive and inefficient gas exchange with hypercapnia and hypoxemia [58]. Hypophosphatemia is present in up to 30% of critically ill patients and may be more common for those with refeeding syndrome [59]. Phosphate deficiency diminishes diaphragmatic muscle function and adversely affects the hemoglobin–oxygen dissociation curve by limiting the production of adenosine triphosphate and 2,3-diphosphoglycerate. Hypoalbuminemia, associated with critical illness and malnutrition, leads to an expansion of extracellular fluid and increased interstitial lung fluid or pulmonary edema. These factors negatively affect the efficiency of the pulmonary system and place patients with lung disease at risk for respiratory failure. Malnutrition also adversely influences the production of secretory IgA, alveolar macrophage recruitment and function and clearance of bacteria from the upper respiratory tract placing patients at risk for nosocomial pneumonia, the most common fatal infection among hospitalized individuals [60].

Energy and Protein Requirements During Pulmonary Disease

Indirect calorimetry is a clinical tool by which measurements of respiratory gas exchange are used to determine energy requirements and substrate utilization for a given subject. It continues to be the gold standard for establishing nutritional goals. Substrate utilization is the ratio of oxygen consumed to carbon dioxide produced for a given macronutrients and is referred to as the respiratory quotient (R/Q). The oxidation of fat, protein, and carbohydrate produces an R/Q of 0.7, 0.8, and 1.0, respectively. Ideally, the R/Q of a given patient should approximate 0.85 to reflect metabolism of mixed substrates. When carbohydrate or total calorie provisions exceed energy requirements, R/Q levels rise above 1.0 to suggest fat synthesis. An R/Q of less than 0.7 is indicative of inadequate nutritional support with breakdown body fat and protein stores from adipose and lean tissue. This information is useful for the adjustment of fuel mixtures within the nutrient prescription to avoid potentially harmful effects of under or over feeding the ventilator-dependent patient. Underfeeding energy may increase risk of infection, prolong ventilator dependence, delay wound healing, and increase overall hospital morbidity and mortality, whereas overfeeding energy needs is
associated with several metabolic, hepatic, and respiratory complications, including increased carbon dioxide production with inability to wean from mechanical ventilation. Studies comparing estimates of energy requirements by predictive formulas have found a poor correlation with measured energy expenditure; only 25% of hospitalized patients received calories within 10% of energy requirements [61,62]. Although many investigators have recommended using indirect calorimetry to feed critically ill patients, few studies have been able to demonstrate an improvement of clinical outcomes or meaningful endpoints. In one such study, 130 mechanically ventilated patients who were expected to stay in the ICU for at least 3 days were randomized to receive energy as measured by indirect calorimetry or 25 kcal/kg/d [63]. Nutrition support was provided as enteral tube feeding with additional calories being given as PN when the daily energy goal was not met. The group fed based on indirect calorimetry had a trend toward lower hospital mortality (32.3% vs. 47.7%, \( p = 0.058 \)); however, this group was also found to have fewer ventilator free days and required a longer stay in the ICU compared to controls. As previously discussed, current clinical guidelines, that are endorsed by the Society of Critical Care Medicine and the American Society for Parenteral and Enteral Nutrition (SCCM/ASPEN), suggest that indirect calorimetry be used to determine energy requirements when available and in the absence of variables that effect the accuracy of these measurements (such as \( \text{FiO}_2 > 60\% \)) or when these measures cannot be made, published predictive equations or simplistic weight-based equations (25 to 30 kcal/kg/d) should be used to determine energy needs [9].

The provision of IV carbohydrate in excess of 5 mg per kg per minute to severely stressed patients increases carbon dioxide production (\( V \cdot CO_2 \)) and may delay weaning from mechanical ventilation. Jih et al. reported the case of a septic ARDS patient who developed increased respiratory distress and hypercapnic acidosis in response to hypercaloric carbohydrate infusion [64]. Hypercapnia resolved as carbohydrate and total calories were decreased to levels consistent with indirect calorimetry measurements of REE. Others have shown that total caloric intake has more of an impact on respiratory function for mechanically ventilated patients than excessive carbohydrate calories [65]. No differences of (\( V \cdot CO_2 \)) was observed upon variation of carbohydrate provisions with consistent total caloric intake (1.3 \( \times \) REE). In contrast, increasing total caloric provisions (1.5 to 2.0 \( \times \) REE) with fixed carbohydrate content led to a significant and progressive increase of (\( V \cdot CO_2 \)).
The substitution of fat for carbohydrate calories may lower $R/Q$ and decrease $(V \cdot CO_2)$ to ease weaning from the ventilator [66]. The use of IV fat emulsions (IVFE) is not without its drawbacks, however. Rapid infusion of IVFE may adversely affect gas exchange by decreased rate of clearance, deposition of lipid particles within the reticuloendothelial system, and subsequent reduction of pulmonary diffusion capacity. This effect is most often seen among patients with existing pulmonary dysfunction and with rates of lipid administration more than 0.11 g/kg/hr [67]. There is also concern that higher infusion rates of IVFE may result in immune dysfunction since the products available in the US are manufactured using soybean oil, which is rich in the omega-6 polyunsaturated fatty acids linoleic acid (LA). Large amounts of LA lead to the production of prostaglandins and eicosanoids that favor vasoconstriction and increased inflammation that decreases bacterial clearance from systemic circulation and increases uptake of bacteria by the lungs [68]. Given these concerns, Battistella et al. randomized 57 trauma patients requiring total PN to receive a formula with or without IVFE for 10 days [69]. They found that patients who received IVFE had a significantly greater length of ICU and hospital stay, longer duration of mechanical ventilation, and higher incidence of infection. The results however were criticized because the two groups did not receive isocaloric feeding (21 vs. 28 kcal per day) and it is possible that the excess calories were responsible for the adverse outcomes rather than exposure to IVFE. A meta-analysis of 12 RCT that compared soybean oil based IVFE to soybean oil sparing formulas in 806 patients found a nonstatistical trend toward a reduction of mortality and an increase in the length of mechanical ventilation and ICU length of stay [70] for soybean sparing formulas. There were no significant effects on infectious complications. As a result of these studies, the intersociety clinical guidelines for critical care suggest withholding or limiting soybean oil IVFE during the first week following initiation of PN to a maximum of 100 g per week (often divided into 2 doses per week if there is concern for essential fatty acid deficiency) [9].

Protein requirements of critically ill patients with pulmonary failure are elevated in accordance with the hypercatabolism of stressed states. A prospective observational study of mechanically ventilated patients demonstrated a 50% decrease in 28-day mortality for nonseptic patients when >1.2 g per kg protein was received in conjunction with energy targets [71]. In a similar study a stepwise decrease of 28-day mortality was demonstrated with increased protein provision (group 1: 0.79 g per kg, 27% mortality; group 2: 1.06 g per kg, 24% mortality; group 3: 1.46 g per kg, 16% mortality) [72]. Guideline recommendations suggest that protein intake range from 1.2 to 2.0 g/kg/d of actual body weight [9]. Unfortunately, an increase in ventilatory drive and minute ventilation
may be seen with protein infusion. It is therefore recommended that protein provisions be advanced slowly with close attention to ventilatory drive for mechanically ventilated patients. Serum protein markers, such as albumin, prealbumin, transferrin, and CRP, are not reliable for determining adequacy of protein provision in the critical care setting for patients with ongoing inflammation [9].

Nutritional Assessment During Pulmonary Disease

Malnutrition, which is typically defined for COPD patients as a BMI of less than 20 kg per m², is an important co-morbidity with an incidence of approximately 20% to 40% [58,73]. The evidence for using this cutoff-point to identify patients at nutritional risk is supported by a multicenter study of hospitalized patients with COPD that found underweight patients with a BMI < 20 kg per m² have a significantly lower FEV(1) when compared to patients who were overweight or obese [74]. To determine the impact of nutritional status on mortality, the investigators followed patients for 2 years after initial discharge and found that there were fewer deaths in overweight (BMI 25 to 30 kg per m²) subjects compared to those who were underweight. For the 49 of 261 subjects that died (19%), this result remained significant after adjustment for FEV(1) with a hazard risk ratio 2.6 (95% CI 1.3 to 5.2). The importance of nutritional status is also supported by its inclusion in the BODE (BMI, airflow obstruction, dyspnoea and exercise capacity) index, a grading system that has been shown to be better than the FEV1 for predicting the risk of death from any cause in patients with COPD [75]. The impact of nutritional intervention has been demonstrated in two meta-analyses of long-term trials of ambulatory malnourished patients with COPD. These reports have demonstrated that when given for two or more weeks, oral and enteral supplements lead to significant gain of weight, lean body mass, fat mass, respiratory muscle strength, physical endurance, and quality of life [76,77].

In regard to defining nutritional status in the ICU, Faisy et al. compared changes of bioelectrical impedance analysis (BIA) with various anthropometric and biologic parameters among patients with COPD and acute respiratory failure [78]. BIA more accurately detected alterations of nutritional status for patients requiring mechanical ventilation, whereas anthropometric data were inconclusive. Low serum albumin levels were also significantly associated with increased mortality among patients in this study. Others have found that weight loss and low percentage of ideal body weight can significantly predict the need for mechanical ventilation among hospitalized COPD patients [79]. Weight changes, serum albumin levels, and BIA, when available, are thus valuable tools in assessment of nutritional status and prediction of outcomes for patients with severe
respiratory insufficiency. BIA more accurately identified COPD patients at risk for respiratory failure because low fat free mass, measured with this technique, more accurately identified patients who have a low body weight with low lean body mass (60%), low body weight with a normal lean body mass (20%) and a stable body weight with low lean body mass (20%) [80].

It has been suggested that all patients admitted to the ICU undergo nutritional assessment utilizing a scoring system that examines both nutritional status and disease severity [9]. The Nutrition Risk Screening (NRS) 2002 and NUTRIC score fulfill both of these criteria and have been clinically validated [81,82]. NRS 2002 assigns points for nutritional status (0 to 3) and severity of illness (0 to 3), where 0 = absent, 1 = mild, 2 = moderate, and 3 = severe, and an additional point for age of 70 years or more. NUTRIC score assigns a range of points for age, APACHE II, SOFA, number of comorbidities, and length of stay in the hospital prior to ICU admission. Patients at high nutrition risk are identified by values of ≥5.

Enteral and Parenteral Nutrition for Patients with Pulmonary Disease

Nutritional support is an important component of the care of patients with respiratory failure and acute lung injury (ALI). Several recently performed studies in this cohort of patients serves as the basis for the current version of the SCCM/ASPEN clinical guidelines for critical care [9]. New findings have helped to clarify when nutritional support should be initiated, when trophic versus full enteral feeding should be used, and when PN should supplement enteral tube feeding or be given as a sole source of feeding. The decision on when and how to provide nutrition support requires assessment of the patient’s nutritional status and disease severity, functional integrity of the gastrointestinal tract, and the anticipated duration of mechanical ventilation.

EN is the preferred route for feeding patients with respiratory failure because it maintains the mass and function of the intestinal tract, reduces bacterial translocation and the risk of sepsis, reduces the systemic immune response, is lower in cost compared with PN, and is associated with better clinical outcomes [83]. Severe complications are fairly uncommon and include aspiration pneumonia, GI intolerance, electrolyte abnormalities, and intestinal ischemia. An update of the SCCM/ASPEN guidelines meta-analysis of 21 randomized control trials comparing early versus delayed EN found significant reduction of mortality (RR = 0.70;
95% CI 0.49 to 1.0; \( p = 0.05 \) and infectious morbidity (RR = 0.74; 95% CI 0.58 to 0.93; \( p = 0.01 \)). Based on these results it is recommended that EN be started in 24 to 48 hours for critically ill patients with ARDS/ALI and for those expected to need mechanical ventilation for \( \geq 72 \) hours [9].

Trophic feeding is defined as EN that provides 10 to 20 kcal per hour and is believed to be of a sufficient amount to prevent mucosal atrophy and maintain gut integrity. It is primarily given for up to 7 to 10 days to patients who are expected to require mechanical ventilation for \( \geq 72 \) hours and whose nutrition risk stratification is from low to moderate [9]. This recommendation is in part based on two open label, randomized controlled trials which hypothesized that initial trophic feeding for up to 6 days would be as effective as full EN and would have fewer gastrointestinal complications [84,85]. These studies include a single-center trial that enrolled a heterogeneous population of 200 patients with acute respiratory failure [84] and a multicenter trial that enrolled 1,000 patients with ARDS/ALI [85]. Patients given trophic feeding received 300 to 400 kcal per day while the full feeding group received 1,400 kcal per day, which approximated 15% and 75% of the calculated energy requirements, respectively. It was found that both groups had a similar number of ventilator-free days, 60-day mortality, and incidence of nosocomial infections, while the group receiving trophic feeding had a lower incidence of elevated gastric residual volumes and diarrhea. The larger multicenter trial has been criticized for underdelivery of protein (0.6 to 0.8 g/kg/d) and that study patients were moderately critically ill and had a shorter LOS in the ICU, potentially indicating lower nutritional risk [9].

Supplemental PN should not be given to ICU patients at low to moderate nutrition risk during the first week of nutrition support. A large multicenter randomized controlled trial of 4,640 patients, comparing initiation of PN at 48 hours versus PN started after 8 days, demonstrated that the late-initiation group had a significantly lower requirement for mechanical ventilation and renal replacement therapy, fewer infections and incidence of cholestasis, and greater likelihood of being discharged from the ICU and hospital alive [86]. A small randomized controlled trial that specifically investigated the benefit of early PN initiation during ALI was stopped after enrolling 78 subjects because of a significant greater hospital mortality in the early PN group [87].

One should endeavor to provide the full caloric goal within 2 to 3 days of admission to the ICU for patients at high nutrition risk or with severe malnutrition [9]. Though there are no randomized controlled trials to support this recommendation, a large observational study of critically ill patients found significantly lower mortality for high risk patients who received >80% of their goal energy [88] compared to those that did not. EN is most appropriate for reasons that have been discussed; however, for patients with poor tolerance to tube feeding or in those requiring
significant vasopressor support the balance of protein and energy requirements should be delivered through the use of PN. The benefits and safety of PN for this group of patients has been demonstrated by studies where protocols provided appropriate doses of energy and protein, achieved good glycemic control, and in some instances, allowed cautious feeding of patients at risk for refeeding syndrome. A randomized multicenter controlled trial of early PN in 1,372 critically ill patients with a relative contraindication to EN compared PN, as the sole source of nutrition support, to standard of care where subjects received EN as tolerated [89]. The study found no differences of ICU and hospital length of stay or 60-day mortality but did note a significant decrease of the duration of mechanical ventilation for the PN group. In a similarly designed study comparing early PN (without EN) to early EN for patients without a contraindication to tube feeding, a similar incidence of 30-day all-cause mortality was noted for all subjects (primary outcome), a significantly lower incidence of hypoglycemia and vomiting was seen in the early PN group, and no difference was noted for infectious complications, 90-day mortality, and other secondary outcome measures [90]. Finally, a randomized controlled trial of 305 critically ill patients comparing EN supplemented with PN to standard EN, found that patient supplemented with PN had a significantly lower number of nosocomial infections (27% vs. 38% with a hazard ratio of 0.65, 95% CI 0.43 to 0.97; \( p = 0.03 \)) [91]. PN should also be used for patients with low to moderate nutritional risk if nutrient requirements cannot be met because of enteral intolerance after 7 to 10 days and for patients with severe malabsorption. Standard enteral formulas are recommended for most patients with pulmonary dysfunction, even those who are critically ill [9]. Fluid restricted energy-dense formulations that provide 1.5 to 2 kcal per mL should be used for patients with acute respiratory failure who require volume restriction. This includes patients with fluid overload, pulmonary edema, and renal failure. As previously discussed, specialty formulations that have a high ratio of fat to carbohydrate designed to manipulate the respiratory quotient and reduce CO\(_2\) production are not of benefit when energy goals range from 25 to 30 kcal/kg/d. We reserve the use of these products for patients with existing COPD and increasing difficulty weaning off the ventilator. A meta-analysis of six randomized controlled trials that investigated the effect of immune modulating nutrition, which contained fish oil, borage oil, and antioxidants and included reports of mortality, 28-day ICU length of stay and ventilator free days, found no significant effects of this therapy for subjects with ALI/ARDS [92]. The SCCM/ASPEN task force noted significant heterogeneity of these trials based on the method of infusion (continuous versus bolus), the type of oils used and in some instances controls that may have received formulas that had an adverse clinical effect and therefore do not endorse the use of
these products [9]. These products are listed in Table 214.2.

Enteral feeding protocols should be used to increase the likelihood of reaching protein and energy feeding targets [9]. Feeding can be delivered to the stomach for most critically ill patients. Prokinetics, such as metoclopramide and erythromycin, may be considered for patients at high risk for aspiration. Those who are at high risk for aspiration or who have demonstrated intolerance to gastric feeding should be fed beyond the pylorus. These recommendations are based on two meta-analyses of nasogastric versus post pyloric feeding in 1,496 and 1,109 critically ill patients [93,94]. Patients who received feeding distal to the stomach were 30% to 40% less likely to develop aspiration pneumonia, received a greater proportion of prescribed calories, and had lower gastric residual volumes. Mortality, length of ICU stay, and gastrointestinal complications were no different between the groups. Measurement of gastric residual volumes should not be used as part of routine care as results do not correlate with the incidence of regurgitation, aspiration, and aspiration pneumonia [9]. Pitfalls of measuring gastric residual volume include little correlation between large measurements and the development of aspiration pneumonia, lack of standardization between method used to measure its presence, and inconsistent effective prokinetic agents [95]. It is currently advised that volumes of less than 500 mL should not result in termination of enteral feeding potentially leading to greater delivery of enteral feeding to critically ill patients.

Summary of Nutritional Recommendations for Patients with Pulmonary Disease

Malnutrition adversely affects clinical outcomes of patients requiring prolonged mechanical ventilation. Early EN reduces the risk of nosocomial infection and mortality. Trophic feeding provides the same benefits as full EN in patients with a low to moderate nutrition risk with better gastrointestinal tolerance. Full protein and energy requirements should be given in the first 48 to 72 hours after admission to the ICU for patients with severe malnutrition or high nutritional risk scores and to others after 7 to 10 days. If goals cannot be reached with EN then supplemental PN should be provided. Nutritional risk is best determined by using a scoring system that combines assessment of nutritional status and disease severity. Energy requirements are best determined by indirect calorimetry, but when unavailable a simple weight-based equation (25 to 30 kcal/kg/d) may be used. Careful monitoring of intake
and output, weight changes, and respiratory status is required when indirect calorimetry is not available. Protein needs to promote recovery from illness range from 1.2 to 2.0 g/kg/d and should be advanced with caution to avoid worsening respiratory function. Maintenance of fluid balance is also of primary importance for the critically ill patient with pulmonary insufficiency. Concentrated parenteral solutions and enteral formulas should be used as necessary. Sodium restriction is indicated for patients with pulmonary edema or congestive heart failure. Hypophosphatemia may be avoided by supplementation and gradual advancement of nutritional support for severely malnourished patients. Serum phosphorus, potassium, and magnesium levels should be monitored routinely and deficiencies should be corrected aggressively in this setting. Table 214.5 outlines the summary of randomized controlled trials and clinical guidelines in pulmonary disease.

TIDAL VOLUME

\[ VT = \text{Dead space} + \text{Alveolar space} = VD + VA \]

ALVEOLAR GAS EQUATION

\[ PAO_2 = PIO_2 - PaCO_2 R = FIO_2 \left( P_{\text{atm}} - P_{H_2O} \right) - PaCO_2 R = 150 - PaCO_2 R \text{ (room air, sea level)} \]

ALVEOLAR ARTERIOLAR GRADIENT

Normal values (upright, age 25): \(0.21 \times \text{age}\)

ALVEOLAR VENTILATION (L/min)

\[ VE = k \frac{VCO_2}{PaCO_2} \text{ PaCO} = 0.863 \times VCO_2 \text{ (mL/min)} \]

BOHR EQUATION OF DEAD SPACE

Normal values: 0.2–0.3

PHYSIOLOGICAL DEAD SPACE

Normal values: 0.2–0.3

OXYGEN DISSOLVED IN BLOOD (mL/dL)

\[ DO_2 = 0.003 \text{ (mL, O}_2\text{/dL)} \times PaO_2 \text{ (mm Hg)} \]

OXYGEN CAPACITY OF HEMOGLOBIN (mL O$_2$/dL)

Normal values: 17–19 mL/dL
OXYGEN CONTENT OF THE BLOOD (mL/dL)

\[ \text{CO}_2 = \text{DO}_2 + (1.39 \times \text{Hgb} [\text{g/dL}] \times [\% \text{Hgb saturated with } \text{O}_2]) + (1.39 \times \text{Hgb} [\text{g/dL}] \times \text{SO}_2) \]

PERCENTAGE OF SATURATION OF HEMOGLOBIN WITH OXYGEN

Normal values: >95%

\[ \text{SO}_2 = 100 \times \frac{\text{CO}_2 - \text{DO}_2}{1.39 \times \text{Hgb} [\text{g/dL}]} \]

PHYSIOLOGICAL SHUNT

\[ = \frac{\text{QS}}{\text{Q.T}} = \text{Ccapo}_2 - \text{CO}_2 \text{Ccapo}_2 - \text{Cv-O}_2 \]
\[ = 1.39 \times \text{Hgb} [\text{g/dL}] + 0.003 \times \text{PaO}_2 - \text{CaO}_2 1.39 \times \text{Hgb} [\text{g/dL}] \]
Normal values: <5%

COMPLIANCE

\[ = \frac{\Delta V}{\Delta P} (\text{mL/cm H}_2\text{O}) \]

On Mechanical Ventilation

Static compliance = \( C_{st} = V_T \times P_{plateau} - P_{endexp} \)
Dynamic effective compliance = \( C_{dyn} = V_T \times P_{peak} - P_{endexp} \)

During Spontaneous Breathing

Compliance of the lung = \( C_{L} = V_T \times P_{alveolus} - P_{pleura} \)
Compliance of the chest wall = \( C_{WW} = V_T \times P_{pleura} - P_{atm} \)
Compliance of the respiratory system = \( C_{rs} = V_T \times P_{alveolus} - P_{atm} \)

Normal values: \( C_{st} > 60 \text{ mL/cm H}_2\text{O}; \ C_{dyn} > 60 \text{ mL/cm H}_2\text{O}; \ C_{L} > 200 \text{ mL/cm H}_2\text{O}; \ C_{rs} > 100 \text{ mL/cm H}_2\text{O} \)

RESISTANCE—OHM’S LAW

\[ = \frac{\Delta P}{\text{flow}} = \frac{\Delta P}{Q'} \]

Normal values: airway resistance of the lung at functional residual capacity = 2 cm H\(_2\)O/L/sec
WORK-OF-BREATHING

\[ W_{\text{Thorax}} = \int_{t_1}^{t_2} (P_{aw} - P_{atm}) V' \, dt \]
\[ W_{\text{Lung}} = \int_{t_1}^{t_2} (P_{aw} - P_{es}) V' \, dt \]
\[ W_{\text{Chest wall}} = \int_{t_1}^{t_2} (P_{es} - P_{atm}) V' \, dt \]
Normal values: \( W_{\text{thorax}} = 0.5 \text{ kg M/min} \)

LAPLACE’S LAW OF SURFACE TENSION OF A SPHERE

\[ P = \frac{2T}{r} \]

POISEUILLE’S LAW OF LAMINAR FLOW

\[ V' = P \pi r^4 8\eta l \]

OXYGENATION INDEX

\[ \text{FIO}_2 \times \text{Mean Airway Pressure} \times 100/\text{PaO}_2 [6,7] \]

(>8.1 Adult Respiratory Distress Syndrome [ARDS])

P/F ratio

\[ \text{PaO}_2/\text{FIO}_2 \]

#### Acute Physiology Score

PO$_2$/FIO$_2$ ratio (or P(A–a)O$_2$) for intubated patients with FIO$_2$ ≥ 0.5

#### Ventilated anytime during day 1

Y/N

#### ICU admission information

- Admit to ICU from floor
- Transfer to ICU from other hospital
- Admit to ICU from OR/Post Anesthesia Care Unit (PACU)

#### Emergency surgery

Y/N

#### Pre-ICU length of stay (No. of days between ICU and hospital admission)

#### Admitting diagnosis

- If Diagnosis is acute Myocardial infarction (MI) is the patient on thrombolytic therapy?
- Unable to obtain Glasgow Coma Scale (GCS) (due to meds, anesthesia, or sedation)

GCS
Acute Physiology Score (APS)

Pulse (beats/min)
Select heart rate furthest from 75

\[
\begin{array}{c|c}
\text{Range} & \text{Points} \\
\hline
\leq 39 & 8 \\
40–49 & 5 \\
50–99 & 0 \\

Creatinine without Acute Renal Failure (ARF) (mg/dL)

Select creatinine furthest from 1

- ≤0.4
- 0.5–1.4
- 1.5–1.94
- ≥1.95

OR

Creatinine with ARF (mg/dL)

ARF is defined as creatinine ≥1.5 mg/dL as creatinine ≥1.5 mg/dL and urine output <410 cc/d and no chronic dialysis

Urine Output (cc/d)

Total for day

- ≤399
- 400–599
- 600–899
- 900–1,499
- 1,500–1,999
- 2,000–3,999
- ≥4,000

BUN (mg/dL)

Select highest BUN

- ≤16.9
- 17–19
- 20–39
- 40–79
- ≥80

Sodium (mEq/L)

Select sodium furthest from 145.5

- ≤119
- 120–134
- 135–154
- ≥155

  diagnostic objectives for, 29–31
  hemorrhage, 30
  idiopathic intracranial hypertension, 30
  infection, 30
  myelography, 31
  neoplasms, 30–31
  normal-pressure hydrocephalus, 30
  other neurologic disorders, 31
  shunt malfunction, 30
  techniques for, 32–35
    cisternal puncture, 34
    lateral cervical puncture, 33–34
    lumbar drainage, 35
    lumbar puncture, 32–33, 32f
    reservoirs/shunts aspiration, 34–35, 34–35f
    ventriculostomy, 35
  therapeutic intervention with, 31
    drug therapy, 31
    fistulas, 31
    intracranial hypertension, 31
Cerebrovascular disease, 1354–1363
  intracerebral hemorrhage, 1360–1363
    cerebellar, 1362
    clinical manifestations of, 1361
    diagnosis of, 1361
    differential diagnosis for, 1361–1362
    lobar, 1361
pathophysiology of, 1360–1361
pontine, 1362
primary, 1360
in putamen, 1362
specific syndromes of, 1362
thalamic, 1362
treatment of, 1362–1363
ischemic, 1354–1360
anatomic categories of, 1354
cardioembolic stroke prevention, 1358

differential diagnosis for, 1355, 1356f, 1357
laboratory evaluation of, 1357
pathophysiology of, 1354
radiologic evaluation of, 1357, 1357f
randomized controlled clinical trials, 1360
stroke prevention for, 1358
stroke treatment trials, 1359
supportive therapy for, 1358

treatment of, 1357–1360
underlying mechanism of, 1354–1355, 1356f, 1356
Certolizumab, 627
Cervical cancer, 586
Cervical injuries, 374
Cervical spine injury, 74

CGs poisoning. See Cardiac glycosides poisoning
Charcoal hemoperfusion, 1083
Charcot-Bouchard aneurysms, 1361
Chediak-Higashi syndrome, 814
Cheese reaction, 1000
Chelation agents, for treatment for internal radiation contamination, 1184, 1185
Chelation therapy, in arsenic poisoning, 1048
Chelators, 1141–1142

Chemical agents of mass destruction, 1169–1177
blood agents as, 1174
choking agents as, 1175–1176
classification of, 1171
cyanide as, 1174–1175
decontamination of, 1170–1171
detection of, 1170–1171
history of, 1170
nerve agents as, 1171–1173
eyes with, 1172
gastrointestinal system with, 1172
management of, 1172
nervous system with, 1172
nonlethal incapacitating agents as, 1176–1177
pulmonary agents as, 1175–1176
vesicants as, 1173–1174
Chemical asphyxiants, 1635, 1636t
Chemical burns, 1040
Chemical warfare agents, 1040
Chest computed tomography, 385–386
Chest physiotherapy, 1547
Chest radiographic examination, 1650–1651
abnormalities of pleura, mediastinum, and diaphragm
  empyema and peripheral lung abscess, 1663–1664, 1664f
  pleural effusion, 1661, 1662f, 1663, 1663f
  postpneumonectomy space and bronchopleural fistula, 1664
  subpulmonic effusion, 1661f
cardiac abnormalities
  hemopericardium, 1665
  pericardial effusion, 1665, 1665f
tamponade, 1665
extrapulmonary structures, 1671
lung parenchyma, evaluation of
  acute respiratory distress syndrome, 1658–1659, 1659f
  aspiration, 1660
  atelectasis and pneumonia, 1659–1660
  congestive heart failure, 1656–1658
densities of, 1655–1656
  fat embolism, 1660–1661
  pulmonary edema, 1656–1658, 1657–1658f
pulmonary thromboembolism and infarction, 1670–1671, 1670–1671f
trauma
  extra-alveolar air and signs of barotrauma, 1667–1670, 1668–1670f
  hematoma, 1667
  pulmonary contusion, 1667
  traumatic diaphragmatic hernia, 1667, 1668f
  traumatic lung cyst, 1667
vascular trauma, 1665–1667
tubes and catheters, evaluation of
  central venous catheters, 1652, 1652f, 1653f
  chest tubes, 1654, 1655f
degree of inflation of lung, 1651f
endotracheal tubes, 1651–1652, 1651f
intra-aortic balloon pump, 1653, 1655f
nasogastric tubes, 1654, 1656f
Swan-Ganz catheters, 1652–1653, 1653f, 1654f
tracheostomy tubes, 1651f, 1652
transvenous pacemakers, 1654–1655, 1656f
Chest radiographs, tuberculosis in, 776f, 777
Chest thump, 133
Chest tubes, insertion and care, 107–112
complications of, 110, 111t
contraindications for, 108
equipment for, 109t
indications for, 107–108, 107t
  chylothorax, 107t, 108
  empyema, 107t, 108
  hemothorax, 107t, 108
  pleural effusion, 107t, 108
  pneumothorax, 107–108
management of, 110–11
pleural anatomy/physiology, 107
pleural effusion scanning technique, 112
pneumothorax, 112
removal of, 111
technique for, 108–110, 109–110f
Chest wall
  flail chest, 387
  restriction, 1510
  rib fractures, 387
  scapular fracture, 388
  scapulothoracic dissociation, 388
  sternal fracture, 388
Child abuse, 1563
Chloral hydrate poisoning, 1122–1123
Chlorate salts poisoning, 1102–1103
Chlordane, 1091
Chlordiazepoxide, 1119, 1120t, 1154
  elimination half-life of, 1120t
Chloride salts, 2092
 Chlorine gas, 1176
Chlorophenoxy herbicides poisoning, 1102
  clinical toxicity of, 1102
  management of, 1102
  pharmacology of, 1102
Chlorpromazine, 1007t
Cholestatic jaundice, 1010–1011
Cholesterol, 105
Cholesterol emboli, 1961–1962
Cholesterol embolism, 620–621, 655–656, 656f
Choline and magnesium salicylate, 1112t
Cholinergic antagonists, 1572
Cholinergic poisoning
  acetylcholinesterase inhibitors to treat Alzheimer’s disease, 1032
  clinical manifestations of, 1029–1030
  diagnostic evaluation of, 1030–1031
  inhibition of, 1029, 1029t
  management of, 1031–1032
  nerve agents used in warfare, 1032
  pharmacologic effects of, 1029t
  pharmacology of, 1028–1029
  symptoms of, 1029, 1030t
Cholinergic syndrome, antidote for, 943t
Cholinergic toxicity, toxicologic differential diagnosis for, 1031

Choline salicylate, 1112t
Cholinesterase inhibitors, 1028–1029
  for treatment of myasthenia gravis, 1389
Chronic inhalational use of cocaine, 1035
Chronic kidney disease, 1798
Chronic liver disease, 501–502
  ascites, hydrothorax, and hyponatremia, 2036–2037
  clinical manifestations and diagnosis of, 2034–2035
  complications and management, 2035
  etiologies, 2033–2034
  hepatic encephalopathy, 2035
  hepatopulmonary syndrome (HPS), 2038–2039
  hepatorenal syndrome (HRS), 2037–2038
  liver transplantation (LT), 2039
  portopulmonary hypertension, 2038–2039
  spontaneous bacterial peritonitis (SBP), 2037
  variceal bleeding, 2035–2036
Chronic obstructive pulmonary disease (COPD), 1516, 1542
Chronic rejection (CR), 588
Chronic theophylline overmedication, 1081
Churg-Strauss syndrome (CSS), 616–618
Chylothorax, chest tubes insertion for, 107t, 108
CICU. See Cardiovascular intensive care unit (CICU)
Cidofovir, 691, 1189
Cilastatin, 682
Cilostazol, 883
Cine esophagography, 1042
Ciprofloxacin, 685, 738
  for anthrax, 1194
Cisatracurium, neuromuscular blocking with, 24, 24t
Cisternal puncture, 34
Classic aortic dissection
  clinical manifestations of, 1862
  commonly used medications with routes/doses, 1865t
  diagnosis of, 1862–1863
  epidemiology of, 1861
  etiology and pathophysiology of, 1861–1862
  imaging, 1863–1864, 1864t
  intervention, 1865–1866
  management, 1864–1865
  outpatient follow-up and medical therapy, 1866
Clavulanic acid, 680
Clindamycin, 686
Clinical and Laboratory Standards Institute (CLSI), 353–354
The Clinical Institute Withdrawal Assessment for Alcohol (CIWA-A) scale, 1155
Clinical toxicity
  Bupropion, 999–1000

Heat stroke
causes and pathogenesis of
impaired heat loss, 1748
increased heat production, 1748
diagnosis and evaluation of, 1750
differential diagnosis of, 1750
increased mortality, risk factors for, 1750
pathophysiology of, 1748–1749
cardiac effects, 1749
central nervous system effects, 1749
electrolyte effects, 1750
diocrine effects, 1750
gastrointestinal tract effects, 1749
hematologic effects, 1749–1750
muscle effects, 1749
pulmonary effects, 1750
renal effects, 1749
prognosis of, 1752
treatment of, 1750–1752
Heavy metal poisoning, 1045–1057
antidote for, 943t
arsenic, 1045–1048
clinical toxicity of, 1046–1047, 1046t
diagnostic evaluation of, 1047
management of, 1047–1048
pharmacology of, 1045–1046
arsine gas, 1048–1059
clinical toxicity of, 1049
management of, 1049
pharmacology of, 1048–1049
lead, 1050–1053
clinical toxicity of, 1050–1051
diagnostic evaluation of, 1051, 1051t
management of, 1051–1053
pharmacology of, 1050
mercury, 1053–1056
elemental, 1053–1055
inorganic, 1055–1056
organic, 1056–1057
Heliox, 1583. See also Helium-Oxygen
Helium-oxygen, 1545
jet nebulizers, 1546
HELLP syndrome, 848, 848t
Hemarthrosis, 597, 812, 812t
Hematologic malignancies, 897–907
acquired von Willebrand syndrome with, 901
acute lymphoblastic leukemia, 898–899
acute myeloid leukemia, 897–898
acute promyelocytic leukemia, 898–899
chemotherapeutic agents for, 902
complications of, disease and treatment related, 900–907
bleeding, 900
differentiation syndrome, 904
hyperleukocytosis and leukostasis, 900
hyperviscosity syndrome, 900
infections, 902, 904
pulmonary complications, 901–902
toxicities of therapeutic agents, 904–907t
disseminated intravascular coagulation with, 900–901
evidence-based approaches for, 906–907t
indications for ICU admission in, 898t
non-Hodgkin lymphoma, aggressive, 899
other malignancies, 899
outcomes of patients with, in ICU, 898
therapeutic agents for, 905–907
thrombocytopenia with, 901
Hematopoietic cell transplantation (HCT), 561–575, 564f
allogeneic, 562–563
autologous, 562
classification of, 561–563
donor type in, 562–563
intensity of preparative regimen in, 563
stem cell source in, 561–562
complications, 563–575
after myeloablative allogeneic HCT, 564f
graft rejection, 570
graft-versus-host disease, 571–573
infection, 567–570, 569t
regimen related pancytopenia, 563–564
regimen related toxicity, 564–567
epidemiology of, 563
graft-versus-host disease with, 571–573
acute, 570–571
chronic, 571, 572t, 573
classification of, 571t
diagnosis of, confirming of, 573
differential diagnosis of, 573
immunosuppression for, 573, 574t
prevention of, 573
steroid-refractory, 574t, 575
treatment of, 573, 575
indications for, 562t
infection with, 567–570
adenovirus, 570
advances in management of, 569t
cytomegalovirus, 569
before engraftment period, 567
Epstein-Barr virus, 570
evaluation of, 568
following engraftment period, 568
fungal, 568–570
herpes simplex virus, 569–570
late phase, 568
opportunistic, 568
respiratory syncytial virus, 570
treatment of, 568
varicella zoster virus, 570
viral, 569
myeloablative, 563
nonmyeloablative, 563
regimen related toxicity with, 564–567–1943
acute renal failure, 566
acute respiratory distress syndrome, 565
acute upper esophageal bleeding, 564–565
cardiac complications, 566
cerebrovascular events, 566
CNS infections, 566
diffuse alveolar hemorrhage, 565
hemorrhagic cystitis, 566
hypertension, 566
idiopathic pneumonia syndrome, 565
mucositis, 564
sinusoidal obstruction syndrome, 565
skin erythema, 564
toxic encephalopathies, 566–567
risk factors for mortality/morbidity with, 563
stem cell source for, 561–562
bone marrow, 562
peripheral blood, 562
umbilical cord blood, 562
syngeneic, 562
Hematuria, 493
Hemodialysis, indications for, 1077
Hemodynamic/autoregulatory failure, 1961
Hemodynamic monitoring, 228–237
cardiac output measurement in, 228–234
esophageal Doppler for, 228–231, 229f, 230t
pulse contour analysis for, 231–233, 232t
future directions of, 237
oxygen delivery/tissue perfusion, estimation of, 234–237
gastric tonometry for, 234–235
sublingual capnometry for, 235
practice recommendations of, 237
Hemodynamic resuscitation, 337
Hemodynamic support
management of sepsis, 354–355
sepsis management, 354
Hemoglobinuria, 1958–1959
Hemolysis associated with chemical and physical agents
anemia of chronic disease (ACD)/inflammation, 841, 841t
megaloblastic anemia, 841
Hemolytic anemia, 833–835
classification of, 832t
clinical features of, 834
cold agglutinin disease (CAD), 834
drug-induced, 834–835, 835t
immune-mediated, 833–835, 833t
laboratory features of, 833
paroxysmal cold hemoglobinuria, 834
warm autoimmune, 833–834
Hemolytic uremic syndrome (HUS), 493, 847
atypical, 847
typical, 847
Hemophilia, 812–813, 812t
Hemoptysis
bronchoscopy indicated by, 88–89
categories of causes of, 1596t
definition of, 1595
diagnosis of
angiography, 1601
bronchoscopy, 1600–1601
computed tomography, 1600–1601
general considerations, 1598
routine evaluation, 1598–1599, 1598t
special evaluation, 1601
differential diagnosis of, 1601
differential features of pseudohemoptysis, 1595t
etiology of
idiopathic hemoptysis, 1597
massive hemoptysis, 1597
nonmassive hemoptysis, 1597
idiopathic hemoptysis, etiology, 1597
massive hemoptysis, 1595
common causes of, 1597t
definitive care, 1602
etiology, 1597
nonmassive hemoptysis
definitive care, 1602
etiology, 1597
pathogenesis, 1597–1598
pseudohemoptysis, 1595, 1595t
special evaluation of, 1599t
treatment of
definitive care, 1602–1603
supportive care, 1601–1602
Hemorrhage, physiologic responses to, 335–337, 493
coagulopathy, 336–337
hemodynamic, 337
hemostasis in, 337
immunologic, 338
metabolic, 337–338
oxygen delivery in, 337–338
surgical control of, 340
systemic adjuncts, 340
Hemorrhagic shock
resuscitation, 340–341
utility of ultrasonography for diagnosis of, 339
Hemostasis, 337
acquired coagulation disorders, 1203–1207
acquired hemophilia A, 818
anticoagulant drugs and, 814
cogulopathy of liver disease, 816
direct thrombin inhibitors, 815
disseminated intravascular coagulation, 816–817, 817t
heparins, 814
super warfarins, 815
trauma-induced coagulopathy, 817–818
vitamin K deficiency, 815–816
warfarin, 814–815, 815t
acquired platelet disorders/dysfunction, 818–819
hematologic disorders, 819
medications affecting, 818–819, 818t
uremia, 819
bleeding patient, approach to, 807–808
cell-based model of, 807, 808f
congenital disorders of, 810–813
hemophilia, 812–813, 812t
von Willebrand disease, 810–812, 810t, 811t
laboratory assays of, 808–810, 809t
mixing studies, 810
platelet function, evaluation of, 808–809
reptilase time, 809–810
secondary hemostasis, evaluation of, 809
normal, 807, 808f
other acquired bleeding disorders, 819–820
acquired FII (prothrombin) inhibitors, 820
acquired FV inhibitors, 820
acquired FX deficiency, 820
acquired vWD, 819
primary, 808–810, 808f
rare congenital coagulation disorders, 813–814
  Bernard-Soulier syndrome, 814
congenital fibrinogen disorders, 813
congenital qualitative platelet disorders, 814
factor V and VIII deficiency, 813
factor V deficiency, 813
factor VII deficiency, 813
factor X deficiency, 813
factor XI deficiency, 813–814
factor XIII deficiency, 814
Glanzmann thrombasthenia, 814
prothrombin deficiency, 813
storage pool diseases (SPD), 814
vitamin K-dependent factor deficiencies, 814
secondary, 808–810, 808f
thrombin clotting time (TCT), 809–810
Hemothorax, 339, 389
cHEST TUBES insertion for, 107, 108
examination for, 395
Heparin-associated thrombocytopenia (HAT), 58
Heparin-induced thrombocytopenia, 845–846
diagnosis of, 845–846
prediction rule for, 845f
treatment of, 846, 846f
Hepatic dysfunction
bilirubin metabolism, 2029
blood flow, 2028–2029

Lavage
bronchoalveolar, 668
closed percutaneous technique for, 191–1992
complications with, 191
indications for, 190–191
interpretation of results of, 192–193, 193
open technique for, 192
techniques for, 191–192
contraindications to, 191–192
peritoneal, 190–193
semiclosed technique for, 192
Lawrence suprapubic catheter, 201
LDH (Lactate dehydrogenase), 104, 108
LDLT (Living donor liver transplant), 500
Lead poisoning, 1050–1053
  clinical toxicity of, 1050–1051
  diagnostic evaluation of, 1051, 1051t
  management of, 1051–1053
  pharmacology of, 1050
LEAP (Lower Extremity Assessment Project), 408
LEF (Leflunomide), 625
Leflunomide (LEF), 625
Left atrial pressure, 97–98
Left ventricular assist devices (LVADs), 528, 736
Left ventricular remodeling, myocardial infarction, 1838
LES (Lower esophageal sphincter), 1557
LET (Lipid emulsion therapy), 1148t
Leukapheresis, 928
Leukopenia, 606, 688
Leukostasis, 900, 915
  etiology of, 915
  physiology of, 915
Levalbuterol, 1543
Levetiracetam, 993
Levitronix CentriMag, 528
Levofloxacin, 669, 670, 685
Librium, 1120t. See also Chlordiazepoxide
Lidocaine, 975t, 979–980, 979t
Lightning injuries, 1406
Linezolid, 670, 687, 738, 759
Lipid emulsion, 1018
Lipid emulsion therapy (LET), 1148t
Lipid-laden macrophages, 1561
Lipopolysaccharide (LPS), 354
Liquid crystal display (LCD) thermometers, 211
Listeria monocytogenes infections, in pregnancy, 1475
Lithium, 1074
  intoxication, 1075
Lithium poisoning, 1074–1078
  classification for severity of, 1075
  clinical manifestations of, 1075–1076
  common features of, 1075t
  diagnostic evaluation of, 1076–1077
extracorporeal treatment (ECTR) for, 1078f
management of, 1077, 1078f
neurotoxic effects of, 1075
pharmacology of, 1074–1075
symptoms and signs of, 1075
Liver failure, 2106
acute liver failure. See Acute liver failure (ALF)
acute-on-chronic liver failure
definition and features, 2048
treatment and management options, 2048–2049
energy and protein requirements, 2107–2108

Ventilator-associated pneumonia (VAP), 666, 1516
  bronchoscopy indicated by, 89
Ventilator-induced diaphragmatic dysfunction (VIDD), 1510
Ventilator-induced lung injury (VILI)
definition of, 1509
heart-lung interaction, 1509–1510
pathophysiology of, 1509
prevention, 1509
ventilator-induced diaphragmatic dysfunction (VIDD), 1510
ventilator settings according to disease type, 1510
Ventricular arrhythmias
accelerated idiopathic ventricular rhythm (AIVR), 1811–1812
arrhythmias in stress-induced cardiomyopathy, 1812
monomorphic ventricular tachycardias (VT), 1808–1811
polymorphic ventricular tachycardia (PMVT), 1807
premature ventricular contraction, 1811
STEMI, 1782–1783
subacute and long-term management, 1812
torsade de pointes (TDP), 1807–1808
ventricular fibrillation (VF), 1803–1084, 1807
Ventricular dysrhythmias, 1036, 1036t
Ventricular fibrillation (VF), 1352
Ventricular reservoirs, 34–35, 34f
Ventricular septal rupture (VSR), 1837
Ventriculostomy, 35
Verapamil, 975t, 1020
Versed, 1120t
Vertebral column, 376
Vesicular monoamine transporters (VMAT), 969
VF. See Ventricular fibrillation (VF)
VHF. See Viral hemorrhagic fevers (VHFs)
Video-assisted thoracoscopic surgery (VATS), 386–387
Video capsule endoscopy (VCE), 2009
Vigabatrin, 993–994
VILI. See Ventilator-induced lung injury (VILI)
Viral hemorrhagic fevers (VHFs), 850, 850t
Viral infections
therapy for, 690–691, 690t
acyclovir, 690–691
anti-influenza agents, 691
cidofovir, 691
foscarnet, 691
ganciclovir, 691
Viral pathogens, 352
Visual Analog Scale (VAS), 10
Vitamin K deficiency, 815–816
Vitamin K epoxide reductase complex (VKORC), 892–893
Vitamin K therapy, for anticoagulant toxicity, 1095–1096
Vitamins, parenteral and enteral nutrition, 2092–2093
VKORC (Vitamin K epoxide reductase complex), 892–893
VMAT. See Vesicular monoamine transporters (VMAT)
Volatile substances of abuse (VSA), 1059. See also Hydrocarbon poisoning
von Willebrand disease, 810–812, 810t, 811t
Volume assist-control ventilation, 1506t
Volume assured pressure support (VAPS), 1504
Volume-synchronized intermittent mandatory ventilation (V-SIMV), 1501, 1501f
Volume-targeted mode, 1508f
Vomiting, 1082
Voriconazole, 689
VRE (Vancomycin-resistant enterococci), 677, 686, 738
VRSA (Vancomycin-resistant S. aureus), 677, 686
VSA. See Volatile substances of abuse (VSA)
VSR. See Ventricular septal rupture (VSR)
VTE. See Venous thromboembolism (VTE)
VZV (Varicella-zoster virus), 496, 650–651, 690

Walled-off pancreatic necrosis (WOPN), 2064
definition of, 2063
Warfarin (Coumadin), 814–815, 815t, 889
clinical indications for, 893t, 894
complications and reversal of effect on, 894
Warfarin-induced skin necrosis (WISN), 655
WBI. See Whole-bowel irrigation (WBI)
Weakness, ICU-acquired, 1392–1394
Wegener’s granulomatosis, 618
Wernicke’s encephalopathy, 1346
West African Outbreak, 800
West Nile virus (WNV), 767
Wheezing, differential diagnosis of, 1569, 1569t
Whole-bowel irrigation (WBI), 942
for iron-overdosed patient, 1068
Widow spider envenomations, 1128t, 1131–1132
antivenom therapy for, 1132
clinical manifestations of, 1132
diagnostic evaluation of, 1132
disposition with, 1132–1133
management of, 1132
outcome of, 1132–1133
WISN (Warfarin-induced skin necrosis), 655
Withdrawal syndromes, 1152–1161
baclofen withdrawal, 1158
benzodiazepine withdrawal, 1156–1157
  clinical manifestations of, 1157
  diagnostic evaluation of, 1157
  management of, 1157
  pathophysiology of, 1156–1157
ethanol withdrawal, 1152–1156
  clinical manifestations of, 1153–1154
  diagnostic evaluation of, 1154
  g-hydroxybutyrate withdrawal, 1157–1158
  management of, 1154–1156
  pathophysiology of, 1152–1153
nicotine withdrawal, 1160–1161
opioid withdrawal, 1158–1160
  clinical manifestations of, 1158–1159
  management of, 1159–1160
  pathophysiology of, 1158
sedative-hypnotic withdrawal, 1152
WNV (West Nile virus), 767
Wound closure, 407
Wound complications, 507
Wound irrigation, 407
Wright-Giemsa stain of blood showing nonmotile, 1199f

Xanax, 1120t
Xenotransplantation, 473
Xylene, 1062

Yersinia pestis, plague by, 1198–1201, 1201t
Young and Burgess classification system, 409, 409t

Zanamivir, 691
Zinc phosphide poisoning, 1097–1098
  clinical toxicity of, 1097
  management of, 1097–1098
  pharmacology of, 1097
Ziprasidone, 1007t
ZMapp, 800
Zolpidem poisoning, 1124–1125
Zopiclone poisoning, 1124–1125
Zotepine, 1007t
Z-track technique, 189
